CASE III.—My friend, Dr. R. W. Taylor, kindly refers this case to my clinic, and writes me that he has treated the parents for syphilis. The patient is, as you see, a girl, and her age is four years. She is quite lame, and about the head of the tibia is a moderate amount of infiltration, in the center of which is the opening of a sinus leading to eroded bone. There is no effusion in the joint cavity, and the functions of the knee, so far as flexion and extension go, are perfect. The first signs were observed eighteen months ago, and it was only recently that an incision was made, and this was made without Dr. Taylor's consent or approval. The discharge has been light.

The patient also presents a kyphosis in the lower dorsal region, the deformity not being very marked. This was first recognized a month ago. The child, you will observe, has a strumous habit, and, but for the unquestionable evidences of a specific family history, would be regarded as strumous. With this history, then, a course of treatment, so far as medication goes, will suggest itself. The spine requires a fixation splint, as does also the knee. The danger is that the inflammatory process might extend to the joint and deformity ensue.

The subsequent history of this case is briefly told:

* This case soon manifested a marked change for the better, and then the mother failed to report. Not traced.

The sinus over the head of the tibia closed a few months later, the infiltration subsided, and all that remain now are the cicatrix and a little irregularity in the shape of the head of the bone. The joint functions are perfect.

It would seem that the best thing that happened to the child was the early opening of the abscess, thus giving an exit to pus that will do harm if left long in proximity to a joint.

The vertebral disease did not progress satisfactorily under the use of a steel brace, but, as soon as I could get an opportunity of applying a solid plaster-of-Paris jacket, the case did surprisingly well.

CASE IV.—A strumous looking boy, aged four and a half years, presented at my dispensary class at the hospital in the summer of 1882. He had then a mere fullness over the head of the tibia, accompanied with a little extra heat and moderate tenderness. He limped, favoring the knee, yet the joint functions as to mobility were perfect, and indeed there was no joint lesion to be detected. It was not my privilege to open an abscess in this locality as soon as it appeared, but, in conformity with a line of practice to which the hospital is committed, I had to wait the slow yet steady enlargement of this pus-sac, and I had the opportunity of noting from time to time the gradual encroachment on joint structures, until now we have the characteristic appearances of a typical tumor albus. There are now, in addition to the tibial enlargement, an expansion of the condyles, a fixation of the patella, a general boggy infiltration of all the periarticular tissues. The abscess, after growing to the size of the egg of a goose, began to pain the little fellow considerably, the skin became transparent, and a puncture was permitted. By this time, however, the drainage was done. We have now a sinus and a sanious discharge. The limb is in fair position. We shall have to accept the situation and aim to secure a partially ankylosed joint with the limb in the best position for usefulness. To this end I shall immobilize the parts with a leather splint molded to the limb by soaking in hot water, after which hardening will soon occur. Attention will also be given to constitutional treatment.

Book Notices.

BOOKS AND PAMPHLETS RECEIVED.

Lectures on the Principles and Practice of Medicine. Delivered in Chicago Medical College, Medical Department of the Northwestern University. By Nathan Smith Davis, A. M., M. D., LL. D., Dean of the Faculty and Professor of Principles and Practice of Medicine and Clinical Medicine in Chicago Medical College, etc. Chicago: Jansen, McClurg & Co., 1884. Pp. 896. [Price, \$5.]

A Practical Treatise on the Diseases of the Ear, including a Sketch of Aural Anatomy and Physiology. By D. B. St. John Roosa, M. D., LL. D., Professor of Diseases of the Eye and Ear in the New York Post-Graduate Medical School, and President of the Faculty, etc. Sixth Edition, Revised and Enlarged. New York: William Wood & Co., 1885. Pp. xxii-718. [Price, \$5.50.]

A Practical Treatise on Massage: its History, Mode of Application, and Effects; Indications and Contra-indications. With Results in over Fourteen Hundred Cases. By Douglas Graham, M. D., Fellow of the Massachusetts Medical Society. New York: William Wood & Co., 1884. Pp. x-286. [Price, \$2.50.]

Report of the Secretary of the North Carolina Board of Health, on One Aspect of the Subject of Medical Education, as set forth in the Work of the Medical Examining Board.

Asiatic Cholera in North America. National Conference of State Boards of Health, held at St. Louis, October 13-15, 1884.

The Plaster Posterior Splint in the Treatment of Fractures of the Leg. By George W. Gay, M.D., Boston. Read at the Annual Meeting of the Massachusetts Medical Society, June 10, 1884.

Transactions of the Texas State Medical Association, for 1884.

Eight Meteorological Charts. Issued by the War Department.

Tracheotomy in Croup. By George W. Gay, M.D., Surgeon to the Boston City Hospital. [Reprint from the "Medical News,"]

Transactions of the Colorado State Medical Society, for 1884.

Report of the National Board of Health, for 1883.

Correspondence.

LETTER FROM WASHINGTON.

The Opening of the Medical Schools.—The Advantages for Medical Students in Washington.—The New Secretary of the National Board of Health.—Personal Items.—The Rag Importation Order.—The Medical Association.—The Howard Medical College.

WASHINGTON, November 10, 1884.

THE medical schools have resumed their sessions, all of them with slightly increased classes. The new school, started as a "day" school, has a very few students, perhaps eight or ten, but it is hoped from this nucleus a great institution will be developed. There is an honest difference of opinion as to the time of day when lectures should be delivered, the advocates of the day lectures claiming the force of the established custom in other cities, and that the evening lectures were only instituted here because of the great preponderance of Government clerks among the medical students; on the other hand, the Georgetown and other colleges maintain that the evening, from five to half-past nine, is the best time for lectures, and the day the best time for study and dissections. The singular advantage that the city of Washington possesses to students is less understood than it should be, owing, perhaps, to the absence of a medical journal devoted to its interests. The unrivaled collection of medical books in the library of the Surgeon-General's office, the number and variety of the pathological specimens in the museum, the collection of materia medica in the Smithsonian Institution, the Naval Museum of Hygiene, and the herbarium of the Agricultural Department, together make a field for professional study quite out of the regular rut.

Dr. Hosmer A. Johnson, of Chicago, having resigned from that body, the National Board of Health recommended the appointment of Mr. W. P. Dunwoody to fill the vacancy, and as Colonel George E. Waring, Jr., the secretary, has recently resigned, he has been appointed secretary of the board. Mr. Dunwoody was for some years a clerk in the health office here, and, on the organization of the National Board of Health, was appointed its chief clerk, and subsequently its disbursing clerk. It can not be said that Mr. Dunwoody has ever particularly distinguished himself as a sanitary expert, but he is doubtless equal to Mr. Simon or the other lay members of the board; besides, the literature of the profession is an open book, and he can do as the late Artemas Ward did with the subject of the Cuban insurrection, he can "read Cuba up." However that

may be, it is thought that the redoubtable board will be infused with new life and vigor by the advent of Mr. Dunwoody upon the sanitary stage. The board failed to hold its annual meeting this summer. Under its rules, the executive committee has charge of the correspondence and other acts of the board.

Dr. Basil Norris, of the army, who has been stationed here for so many years as attending surgeon, has been ordered to California as Medical Director of the Department. Surgeon Norris has many warm friends both in and out of the army.

Dr. James F. Hartigan has been appointed a Lecturer on Diseases of Children, and Dr. John W. Bayne Professor of Clinical Surgery, at the Georgetown University—both excellent appointments.

It was flashed across from Paris a few days since that the ragpickers of the Faubourg St. Antoine were those first attacked by cholera, and this was coupled with the statement that the outbreak of the disease was due to imported rags. It will be remembered that our Government, acting on the advice of Surgeon-General Hamilton, suspended the importation of rags from Egypt during the existence of cholera there, and that more recently the order was renewed in view of the appearance of cholera in France. With singular short-sightedness Secretary Gresham modified the order so that it should apply to infected ports only. This had the practical effect of admitting all rags, because of the ease with which they could be transhipped from other ports. It was in vain that the Surgeon-General pointed out this loophole. Mr. Gresham was determined to favor his friends, and issued the order. One of the companies had gone to great expense in fitting up machinery for boiling the rags abroad before baling, and this method was satisfactory to both the Surgeon-General and the Board of Health of New Haven. A little backbone on the part of the Secretary would have forced the rag importers to cause all rags to be disinfected abroad or boiled before being baled, and thus all future trouble might have been avoided; but the ways of the ambitious politician are devious.

It is sincerely hoped that the authoritative statement of the tracing of the Parisian epidemic to imported rags will for ever put at rest such mischievous assertions as that iterated and reiterated by the ragmen, that "no epidemic disease has ever been traced to rags." Even so straightforward a journal as the "Boston Medical and Surgical Journal" has given currency to this assertion, and has been unable to see any wisdom in the governmental order. It is hoped that those eminent sanitarians, the publishers, have not furnished the editorial eye-glasses.

The Medical Association, which is the ethical body of the district, had under discussion at its last meeting the following amendment to its regulations, proposed by Dr. Robert Reyburn:

"Strike out the first paragraph of Section 19, and substitute the following:

"Members of this association shall be allowed to consult with all regular graduates, in good standing, who are not members of this association; provided such graduates are licentiates of the Medical Society of the District of Columbia."

The amendment was opposed by Dr. Lovejoy and Dr. Toner, and, after some discussion, was laid on the table. The effect of the amendment, if passed, would have been to admit to consultation privileges certain graduates of Howard Medical College who were not members of the association. It should be understood that the Howard Medical College is the college for freedmen, and that white men are admitted to the same classes. The fees are quite low, in consequence of the charitable character of the school, and there has been until lately some degree of prejudice against the non-African alumni.

Dr. Horatio R. Bigelow sailed for Europe last week, intending to be absent about two years.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & CO.

Edited by
FRANK F. POSTER, M. D.

NEW YORK, SATURDAY, NOVEMBER 22, 1884.

THE NEW YORK STATE MEDICAL ASSOCIATION.

THE first annual meeting of the New York State Medical Association, held in this city on Tuesday, Wednesday, and Thursday of this week, is a noteworthy event, from whatever standpoint it may be regarded. We prefer to look at it—as this and the succeeding annual meetings of the same body are certain to be looked at when the circumstances that led to the formation of the association have left as few traces of rancor elsewhere as they have in New York—as a most successful meeting for the interchange of views and experiences in the various branches of medical knowledge.

The sessions were well attended from all quarters of the State, and the preponderance of men who had reached middle life showed most unmistakably the interest that is felt in the success of the association. The younger element was by no means lacking, however, and the physicians of the city, whether members or not, were present in sufficient numbers to warrant the statement that the meeting was looked upon by them with a good deal of interest. Moreover, a number of eminent medical men from other States attended the meeting, having come to New York for the purpose.

Concerning the scientific work of the meeting, we can only say that the programme, which we have already published, was, in our opinion, one that we have never known excelled by an organization drawing its members from no greater territory, whether we consider the importance of the subjects presented or the standing of the men by whom they were handled; and that the programme was exceedingly well carried out. Indeed, not only were but very few of the papers set down read by title, but quite a number were read that had not been mentioned in the programme.

In this issue of the journal we publish several of the papers, together with a summary of the general work of the meeting, and we shall shortly publish a number of the other papers. Our readers will therefore be afforded an early opportunity of judging for themselves of the quality of the work done. For our own part, we regard it as admirable.

The New York State Medical Association enters with no faltering step upon a career which we look to see long and honorable. The spectacle of two societies representing the profession of the State need not continue to signify disagreement; we believe that it has already ceased to imply dissension. In this age, "the good men do lives after them," and the mantle of forgetfulness is speedily wrapped around manifestations of acrimony; we are persuaded, therefore, that the profession of the State as a whole are prepared to look upon the achievements of the new association with pride. The State of New

York is a large one, and we see no reason why each of its two societies should not do good work; perhaps, indeed, emulation may lead each one to higher purposes than either, if it occupied the field alone, would aim at.

THE ROYAL COLLEGES OF ENGLAND.

AT the late meeting of the General Medical Council a subject of the greatest importance was discussed, no less a matter than a scheme for uniting the College of Physicians and the College of Surgeons, and requiring students to pass a conjoint examination which should cover all the branches demanded by the separate bodies. We in America can never understand how jealously English medical men cling to those venerable institutions, how every tradition connected with them is tenderly kept alive, and how the idea of mutability is as far removed from their names as from that of the Bank of England. The very aspect of the gloomy old pile in Lincoln's-Inn Fields dispels all thoughts of change and decay; the busts of a long line of illustrious surgeons, which look down from its walls, seem to frown at every innovation.

To speak of one of the royal colleges is to suggest in a word one of the last strongholds of English conservatism. Can it be that this is threatened? It appears so. The Medical Council, by the way, has had a series of lively meetings. There was by no means perfect unanimity regarding the proposal to unite the two extremes of medicine and surgery, and some of the remarks of the distinguished members form spicy reading. The third licensing body, the Society of Apothecaries, which has long been regarded with aversion by its more dignified rivals, was calmly ignored by the Council.

The questions before the Council were as to whether the two colleges should unite their examinations, and as to whether, in so doing, the standard should be lowered. These questions were vigorously discussed, countless propositions and resolutions were offered, and finally it was voted to reserve the decision for a subsequent meeting. The subject of midwifery seemed to prove a *casus belli*; some members were for a special examination in that branch, while others were against it. We remark with surprise that several of the gentlemen appeared to favor a lowering of the standard in this department. We should be very sorry to see any such concession as this made. It is the boast of the two chief examining bodies that they endeavor to raise the student to their level, and not suit their examinations to his deficiencies. It is a curious but characteristic surgical argument against a thorough training in midwifery that many practitioners "do not need it." There is a great deal of useless matter "crammed" for the examinations in surgery, yet no such charge is brought against that branch. It is difficult for us to comprehend the inconsistency of some English examiners who cry down specialists, and yet recommend a special degree in obstetrics.

We are not in a position to sift the matter thoroughly; its salient points are the only ones that we, as foreigners, can consider intelligently. The profession of Great Britain are to be congratulated upon the interest which has been aroused in

regard to this important matter. That the discussion will be productive of good we are sure, although we should regard it as a great misfortune if the present standard of the London examinations was not preserved. The "conjoint scheme" will be a true reform if it clears away some of the dust of ages which covers the customs and traditions of the ancient colleges. We foresee another possible consequence of this new movement—the breaking down of that partition wall which now separates medicine from surgery, and the establishment of broader and more liberal ideas regarding the spheres of the physician and the surgeon. This will not be the work of a day, but the change is sure to come.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 18, 1884:

DISEASES.	Week ending Nov. 11.		Week ending Nov. 18.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	38	13	32	9
Scarlet Fever.....	46	9	49	12
Cerebro-spinal meningitis.....	3	2	8	8
Measles.....	102	13	83	12
Diphtheria.....	72	38	62	35

Yellow Fever in New York.—On Wednesday afternoon it was discovered that the steward of a vessel which reached this port from Costa Rica the day before was dying of yellow fever in a boarding-house in Spring Street. He died after having been taken to the Reception Hospital. The captain of the vessel is reported to have declared to the officials at the Quarantine Station that there was no sickness on board, but the sick man stated that he was attacked on the 8th inst.

A Crematory for New York.—The corner-stone of a crematory was laid at Mount Olivet Cemetery, Long Island, on Wednesday of this week.

Mount Sinai Hospital.—A reception was held at the hospital last Sunday, and the benefactors of the institution were enabled to see the many evidences of the good work it is doing.

Professor Virchow has been elected to the German Parliament.

A French Cholera Commission in Italy.—According to the "Union médicale," M. Jules Aronsson, professor of organic chemistry, is to take charge of a scientific mission to Italy, for the purpose of studying the etiology, the physiological chemistry, and the therapeutics of cholera.

The Death of Dr. Samuel A. Fisk, of Northampton, Mass., took place last Sunday. Dr. Fisk was a prominent member of the Massachusetts Medical Society. He had reached the age of sixty-three years.

Society Meetings for the Coming Week:

MONDAY, November 24th: Medical Society of the County of New York.

TUESDAY, November 25th: New York Dermatological Society; New York Surgical Society; Boston Society of Medical Sciences (private); Buffalo Obstetrical Society (private—a paper on "The Hot Vaginal Douche in Pelvic Disease," by Dr. Fell).

WEDNESDAY, November 26th: New York Pathological Society; American Microscopical Society of the City of New York;

Auburn City, N. Y., Medical Association; Berkshire, Mass., District Medical Society; Cumberland County, Me., Medical Society; New York Society for the Relief of the Widows and Orphans of Medical Men (annual).

THURSDAY, November 27th: New York Academy of Medicine (Section in Obstetrics and Diseases of Women); Roxbury, Mass., Society for Medical Improvement (private).

FRIDAY, November 28th: Yorkville Medical Association; New York Society of German Physicians; New York Clinical Society (private).

OBITUARY NOTES.

Professor Julius Cohnheim.—On the 14th of August, as has already been briefly stated in this journal, Julius Cohnheim died in Leipsic. In him not only Germany, but the whole world of science, has lost one of her most prominent and original thinkers, and those, to whom it was given to know him personally, mourn the loss of a dear and honored friend.

Cohnheim made his first entrance into the scientific world, while an assistant to Virchow, by his investigations on the nerves of the cornea. In the necessary experiments he originated that method of chloride-of-gold staining which has since been so widely employed. At this period, too, he made those discoveries, connected with the emigration of the white-blood globules in inflammation, which at once placed his name in the foremost rank among pathologists. It is an instance of his application and enthusiasm for his work that nearly all the observations which culminated in the discovery of the processes of inflammation were made, as he once told me, before seven o'clock in the morning, the rest of the day being busily occupied in the routine of teaching and making post-mortem examinations at the Pathological Institute. In regard to this, the great discovery of his life—a discovery which had been unceasingly sought after by physicians of all nations, and at all times, since the earliest dawn of medical science—he never failed to show his characteristic modesty, nor ever neglected, in his lectures or writings, to point out that Waller, in England, had forestalled him with the same observations, but that they had been, unfortunately, totally ignored and forgotten by the world. Only after he had published his own researches did he become aware of Waller's publication in the "Philosophical Magazine" for 1846 of similar experiments and results. In his researches on inflammation he used that method of direct observation, in transparent portions of the living body, of pathological processes in the very act of their occurrence, which he subsequently developed in his investigations on thrombosis and embolism, on tuberculosis, and other subjects.

Soon after this, his reputation being now firmly established, he was called to a professorship in Kiel. Here he made his well-known researches on thrombosis and embolism, besides completing other minor works.

In 1872 he received an appointment at Breslau, where a larger sphere of usefulness was opened to him, and in 1878 he followed a call to Leipsic. Here he enjoyed increased facilities for work and for intercourse with kindred spirits, and with this university he was connected up to the time of his death. In Breslau and Leipsic many students, attracted by his fame, sought, in his private laboratory, the advantages of working under his guidance and advice, and it is from this period of his life that so many researches bearing the impress of his genius have appeared.

As a pathologist, Cohnheim was a thorough believer in the physiological method of study, and constantly sought to keep before the minds of his pupils the fact that pathology was but morbid physiology. His great work, in two volumes, "Lectures on General Pathology," of which he completed a second edition

shortly before his death, is a thorough exposition of his views and methods of thought. In it physiological pathology has been developed to its widest limits, and the general interdependence of nearly all pathological processes clearly pointed out. It is a masterly and suggestive work, full of sound thought and lucid reasoning, presented in a simple and interesting style of diction. Its influence on the rising generation of pathologists in Germany has been great, and it is much to be regretted that no translator has yet given it to the English-reading public.

In his scientific work he was distinguished by a singular modesty and candor. Always ready to listen to objections, he gladly admitted mistakes when they were pointed out to him. Ever eager for truth, he would often question results whenever, at any time, he suspected his experiments to have been liable to error. Thus his first investigations on tuberculosis, made in the Pathological Institute in Berlin together with Fränkel, led him to believe that the implantation in rabbits and Guinea-pigs of indifferent materials—as pieces of cork or glass, pellets of paper, etc.—had as much effect in causing tuberculosis as inoculation with tubercular material itself, and he published his opinion accordingly. He was afterward led to doubt the validity of his results, surmising that in his experiments an accidental inoculation with tubercular virus might possibly have occurred. He therefore repeated them in Kiel and Breslau, with increased precautions, and under more favorable hygienic surroundings for the rabbits, and found then that tuberculosis resulted only when actual tubercular material had been inoculated. He at once published these now well-known experiments, calling attention to his former errors. It was he who introduced the method of inoculating tubercular virus into the anterior chamber of the eye, where all changes can without difficulty be observed. He found that a period of incubation lasting fourteen to twenty-one days elapsed before miliary tubercles appeared upon the iris, this being followed later by a tubercular invasion of the body generally. This discovery placed the disease in question on as firm a basis regarding its infectious nature as did Koch's later one of the bacillus—a final but not absolutely necessary link in the chain of proof.

He was always inclined to criticise kindly the works of others, and though, if necessary, he emphatically pronounced an opposite view, he yet strove to recognize their good points. In his earlier writings he replied to carping criticisms with a fine sarcasm, which generally was peculiarly ludicrous from its unexpectedness and from its point. In later years, however, he but rarely noticed personal allusions, regarding such attacks with amused indifference.

His was also to an eminent degree that rare talent, which so few possess, of being able to enter fully into the thoughts and plans of others. This faculty led him to generally allow his pupils to pursue such researches as they were themselves most interested in, while he assisted with his advice. In this way he strove to elicit the best thoughts from each, giving to every one that work for which he seemed by inclination and previous study most fitted.

His patience was remarkable. He would listen with great attention to the crudest suggestions, and take infinite pains in explaining his objections, seeking at the same time to find some good and useful points in everything submitted to him. This combination of modesty with patience and genuine kindness made him singularly approachable and companionable. He never made one uncomfortably conscious of his learning and experience, nor willingly caused any one to feel his own ignorance. Indeed, he was so willing to receive knowledge or suggestions from all, and so readily submitted to contradiction and argument, that it sometimes seemed to me as though he might be the pupil, and the pupil the master!

As a teacher his method was perfect. Such clearness, such order, such consecutiveness of thought, and such a grasp of the subject as he showed in his lectures, can hardly be excelled. Those who heard him felt as though they were sitting at the fountain-head itself, not listening to the mere oral repetition of some text-book, but gaining the results of the ripe experience and earnest thought of an original and successful investigator.

Personally he was a most lovable man, inspiring feelings of true affection and esteem in the hearts of all who knew him. His temper, always of a quiet cheerfulness, had also a vein of pleasant humor running through it, and even in spite of great suffering, and in spite of the knowledge of a not very distant end, this temper never changed. He also never complained, rarely spoke of himself, and never of the final issue of his illness, for more than fifteen years he had suffered from gout. Gouty nephritis manifested itself early in the disease, and it was from this and its cardiac complications that he finally died. He was a true philosopher. Once fully knowing the inevitable outcome of his malady, he laid the thought of death aside, so far as any man ever can, and steadily pursued the work that each day brought him.

As a friend and pleasant companion, we who saw him at his home, in the circle of his family, can best appreciate him. Here, aided by a most devoted and amiable wife, he dispensed a gracious and kindly hospitality that charmed all who came within its influence.

Cohnheim was but forty-five years of age when he died. Thus stricken down in the best years of his life, when his powers, already so great, seemed to be ripening to still higher promise, he leaves behind him in the annals of science a record which will for ever keep his name remembered and honored, and in the hearts of his friends and pupils a sweet and dear remembrance.

WALTER MENDELSON.

Proceedings of Societies.

NEW YORK STATE MEDICAL ASSOCIATION.

First Annual Meeting, held in New York, Tuesday, Wednesday, and Thursday, November 18, 19, and 20, 1884.

The President, Dr. H. D. DIDAMA, of Syracuse, in the Chair.

Tuesday's Proceedings.

THE meeting was called to order at the Murray Hill Hotel at 10 o'clock A. M.

The President's Address.—The President, in his annual address, dwelt upon the subjects of progress and conservatism in medicine. The address will be published in full hereafter.

A Committee on Scientific Communications was appointed by the President, consisting of Dr. ARNOLD, Dr. CLARK, Dr. GILLIS, Dr. AVERY, and Dr. CANNON.

The Annual Report of the Council was read by the Secretary.

Delegates from Other States were then introduced and invited to participate in the scientific proceedings, after which the Treasurer, Dr. HINTON, read his report, by which it appeared that \$1,686 had been received, and \$1,002 disbursed.

The Report of the Special Committee on the Organization of District Associations was read by Dr. GOWLEY, and, after some discussion as to possible relations with county medical societies, was unanimously adopted.

An Auditing Committee was appointed by the President, consisting of Dr. PURPLE, Dr. WYCKOFF, and Dr. ORTON.

The Address in Surgery was then read by Dr. E. M. MOORE, of Rochester. Dr. Moore presented some facts in connection with the transfusion of blood, and remarked that the subject, looked upon from any point of view, was in a state of uncertainty. Any surgical procedure, to be widely practiced, must be simple and easily executed, and, if possible, we should be able to extemporize means for its performance if the necessary apparatus was not at hand. He briefly referred to the history of transfusion. As to the use of defibrinated blood, he agreed to the statement which had been made, that defibrinated blood should not be considered as blood. Fresh blood being employed, in order to avoid coagulation the transition should be short, and yet the injection should be neither too rapid nor too forcible. Most operators extended the injection over two or three minutes, in order to prevent too violent shock, but within this time blood would coagulate. Dr. Moore then described an apparatus of his own invention, by which he thought the greater difficulties and dangers of transfusion were overcome. It consisted of a soft-rubber cylinder, to contain the blood, to which a round-pointed needle could be attached for introduction into the vein of the recipient. When the desired amount of blood had been introduced directly from the donor's vein into the rubber cylinder, the walls of the latter were rolled up and compressed by the operator's hand, which forced the contents through the hollow needle into the patient's vein with the desired rapidity. In several cases of transfusion performed by Dr. Moore, the entire time occupied was less than one minute. The influx could be immediately cut off by pushing upon the head of a piston fitting into the hollow needle. The shape of the needle would prevent a coagulum forming on its surface. It could be left in the vein of the recipient, if it was desired to interrupt the operation and begin again, the reservoir and its attachments being cleansed in the mean time. The several patients upon whom Dr. Moore had employed this apparatus for transfusion had been benefited, and all but one of them permanently.

The address was discussed by Dr. TOWNSEND, who confirmed Dr. Moore's remarks concerning one of the cases in which transfusion was performed, which he had seen with him.

The New York County Medical Association.—Dr. WILLIAM DETMOLD, President of the New York County Medical Association, was introduced to the meeting, and made some remarks upon the work which had been done by that association during the past year. His remarks and the titles of the papers read before the New York County Medical Association for the year were ordered upon the minutes.

A recess of ten minutes was then taken, during which the members of the several districts organized, appointing officers for their respective districts for the coming year, and naming a date for an annual meeting.

Dr. J. W. S. GOULEY, of New York, was chosen Member at Large of the Nominating Committee.

Transfusion.—At the afternoon session Dr. J. C. HUTCHISON, of Brooklyn, read a paper on this subject. It will be published in a future issue of this journal.

Dr. ROCHESTER, of Buffalo, discussed the paper, and referred to some cases which went to show that a much smaller quantity of blood was required to produce marked beneficial effects than of saline solutions, and said that there must be something more than the mere dynamic power in the fluid to produce the effect. In cases of cholera in which the patients could be aroused from a moribund condition by the injections of the salines, this might often be of great advantage even if it was but temporary, as it would enable the patient to make a will and attend to other important affairs.

The Duration of Contagiousness after Acute Infectious Diseases was the title of a paper read by Dr. ALFRED L. CAR-

ROLL, of Richmond County. It will be published in full in this journal.

A paper entitled "The Therapeutics of Diphtheria," by Dr. J. W. MOORE, of Albany County, and another entitled "Notes on Dislocation of the Hip," by Dr. FREDERICK HYDE, of Cortland County, were read by title.

Chronic Intestinal Catarrh.—Dr. JOHN S. JAMISON, of Steuben County, read a paper on this subject. He first described the anatomy of the intestinal tract, mentioned old pathological conditions the presence of which might be one of the causes of intestinal catarrh, spoke of the important rôle played by coarse and undigested foods in the etiology of the affection, and also of other inproprieties in diet; likewise of exposure in damp weather, chemical and mechanical irritants, and idiosyncrasy as indirect causes, of disease of the stomach, liver, pancreas, etc. Before the reading of the paper was finished, the President announced that, owing to the large number of papers to be read, the society would have to adhere to the rule to restrict the reading of each paper to thirty minutes.

Progress in Materia Medica and Therapeutics.—Dr. E. R. SQUIBB, of Brooklyn, read a paper with this title. [See page 572.]

The Management of Criminal Abortion was the title of the next paper, by Dr. W. H. ROBB, of Montgomery County. Dr. Robb restricted his remarks to those cases in which gestation was interrupted before the fifth month, and considered the subject under four heads: 1. The best method of controlling hemorrhage. 2. The safest way of removing the entire ovum. 3. The prevention of septiciæmia. 4. The restoration of the woman to health. The means for controlling hemorrhage were both local and constitutional. The constitutional means were the use of ergot and that of digitalis. In extreme cases the drugs should be administered hypodermically, and it might be necessary to give brandy and ether in the same way. He would advise the use of ergot as early as possible, either to control hemorrhage or to produce expulsion of the uterine contents, and he would continue its use until the uterus had contracted after its evacuation. In regard to local measures, he would rely mainly on hot water or ice, the tampon, and the tent. If hot water failed, if there was no decomposition of the ovum, and if the cervix was not sufficiently dilated to admit of the introduction of the finger, he would introduce a tampon, and use carbolized water as a disinfectant. The use of the tent should be preceded by an injection of carbolized water through a rubber tube with openings so directed as to prevent the injection of air into the Fallopian tubes or the uterine sinuses. The uterus should be emptied of all foreign matters as early as possible. For removing the ovum, no instrument could take the place of the finger, if the cervix would admit of its introduction. The artificial evacuation of the uterus should be followed by the use of disinfectants in the form of injections. For restoring the woman to health, hygienic conditions should be attended to and restoration of the general health should be aimed at, pelvic and nervous troubles being managed as they arose. In conclusion, he urged the necessity of physicians using all their influence to discountenance the work of abortionists.

Dr. ELY VAN DE WARKER, of Syracuse, had seen no benefit follow the use of ergot given for the purposes mentioned by the author, and he thought it was wasting valuable time to wait for its action to control hemorrhage. For some time past he had not resorted to the use of tents for dilating the uterine canal; he had succeeded well with the uterine dilator, and he preferred to use it, as it enabled him to introduce his finger.

Dr. MOSES C. WHITE, of New Haven, said that the action of ergot at the third month was not to expel the contents of the uterus, but to cause the blood-vessels of the organ to contract,

thus tending to prevent abortion: hence the use of the drug as a preventive of that accident.

Dr. R. H. SABIN, of West Troy, referred to a case in which the use of the tampon for the control of hæmorrhage after the expulsion of a fibroid seemed to have been the cause of rupture of the uterus, and of the consequent death of the woman.

Chronic Mercurial Poisoning was the title of the next paper, by Dr. CHARLES BULKLEY, of Monroe County, who related a case in which the symptoms suggested to him arsenical poisoning, but disappeared with the temporary removal of a set of false teeth from the mouth, and returned when the use of the teeth was resumed. A like sequence of events had been observed in other cases. Chemical analysis of the teeth showed that the India-rubber base contained mercury, and it was concluded that that had been the cause of the symptoms. He therefore advised against the use of rubber colored with mercury in the formation of plates.

A Case of Acute Lead Poisoning resulting fatally was the title of the next paper, by Dr. SABIN. The patient was a painter, and the symptoms of lead poisoning were severe from the beginning of his last illness, taking on an algid form and leading shortly to death.

Errors of Refraction; the Importance of their Recognition and Correction in Early Life.—Dr. H. E. MITCHELL, of Rensselaer County, read a paper with this title. He began with a brief description of some points in the anatomy of the eye, and of the hardening of the sclera which took place as the child grew older, and directed attention to the mechanism of emmetropia, myopia, hypermetropia, and astigmatism, and to the necessity of correcting the abnormal conditions early in life. The general practitioner could determine, by means of a set of test-types and the optometer, whether or not it was necessary to send a patient to an oculist. The author then described the optometer.

The Dietetic Treatment of Dyspepsia.—Dr. AUSTIN FLINT, of New York, read a paper with this title. [See page 566.]

Double Synchronous Amputations was the title of the next paper, read by Dr. U. C. LYNDE, of Erie County. The author considered the subject from a statistical point of view, most of the cases which he had collected having been those of amputations performed in consequence of railway injuries.

The Functions of the Auricles was the title of a second paper by Dr. LYNDE. He maintained that the auricles were entirely passive, being only the termination of the veins, serving as reservoirs for the blood before it entered the ventricles. Some of his reasons for asserting that the auricles did not contract were: there was no necessity for their contraction; their walls were quite thin; they were covered by a deposit of fat; there were no valves in the large veins; in disease the walls of the auricles became very thin and largely distended, and would rupture if they contracted.

Dr. AUSTIN FLINT, Jr., could not accept the view put forth by Dr. Lynde, that the auricles did not contract, as experiments made by himself and by most physiologists had demonstrated their actual contraction. These experiments had been repeated many times, and there could be no doubt of the fact he had stated. Again, the auricular walls contained muscular fibers, like those of the ventricles, and everybody would acknowledge that the ventricles contracted. The results of experiments were also opposed to the view that the auricles were emptied by a suction force as a result of ventricular contraction.

Dr. MOORE referred to experiments by himself and Dr. Bennett, performed in 1838, which, as well as experiments by others, he thought, positively proved that the auricles contracted.

Dr. FLINT, Sr., said that, in cases of free communication, in consequence of valvular incompetency, between the right ven-

tricle and the right auricle, a jugular pulse was to be noticed with each contraction—that of the ventricle and that of the auricle—the two jugular pulses taking place synchronously with the ventricular and the auricular contraction, respectively. A presystolic murmur, evidently due to active contraction of the auricular walls, afforded further evidence of the correctness of this view.

The subject was further discussed by Dr. Ross, and Dr. LYNDE closed the discussion. The latter said that he had been able to demonstrate the active contraction of the ventricle on introducing a cannula, but that he had always failed to get any evidence of active contraction of the auricle.

On the Use of the Aspirator in Hydrothorax.—Dr. E. D. FERGUSON, of Rensselaer County, read a paper with this title, the object of which was to show that danger attended the use of the aspirator in these cases, especially when the amount of liquid withdrawn was not limited. The aspirator should never be used to completely empty a living, non-retracting cavity. Eight ounces would often be a sufficient amount of fluid to withdraw at a single operation, and certainly, if difficulty of respiration or other symptoms following the withdrawal of fluid from the chest occurred, the operation should be stopped immediately.

A New Procedure in Paracentesis Thoracis was the title of the next paper, read by Dr. THOMAS F. ROCHESTER, of Buffalo. [See page 571.]

The two papers being before the meeting for discussion, Dr. FLINT, Sr., said that he had listened with interest to both of them. He thought that Dr. Ferguson had perhaps rather overdrawn the harm done with the aspirator, but the precaution he had suggested in its use seemed appropriate. He had been particularly struck with the comparison made between completely emptying the pleural cavity of fluid and the entire evacuation of the distended bladder, as, some years ago, he had witnessed a disastrous result in a case of the latter kind.

Dr. E. M. MOORE was of the opinion that Dr. Ferguson had underestimated the benefits to be derived from the aspirator in overestimating the possible harm it might do. He thought Dr. Ferguson had made a good point in speaking of the danger of removing too much of the fluid from the pleural cavity at one time. The instrument, however, was of great value when employed with this precaution in view, and its use should be repeated as often as might be necessary. He had in certain cases resorted to the use of drainage-tubes, but had given them up, as being much inferior to the aspirator. But in certain other portions of the body, as in the abdomen, where the walls would readily collapse on withdrawing the whole of a collection of fluid, the precaution to withdraw only a portion did not apply. He had also seen an unfortunate result, after emptying an over-distended bladder, from hæmorrhage.

Dr. ROCHESTER said, with regard to Dr. Ferguson's paper, that most writers at present spoke of the danger of completely emptying the pleural cavity at one operation. As to the danger of hæmorrhage from blood-vessels of the pleura, he had also known serious hæmorrhage from the lung occur after paracentesis thoracis. Sometimes it happened that, after once withdrawing eight or ten ounces of the pleuritic fluid, the patient went on to complete recovery. In other cases the operation had to be repeated. He always immediately ceased to withdraw fluid if the patient began to complain.

Dr. FERGUSON said he had wished to emphasize the importance of withdrawing only a small amount of fluid, without waiting for the patient to complain. In some cases it became necessary to use a drainage-tube, and he had no doubt that loss of life had been avoided by this means in many cases.

Dr. W. C. B. FIELDFIELD, of Boston, called attention to the fact

that Dieulafoy, some years ago, when he first introduced his aspirator, pointed out the necessity of withdrawing only a small amount of the fluid from the pleural cavity at each operation.

The PRESIDENT asked, with regard to Dr. Moore's statement, that a large majority of patients with pleurisy got well, how it was that so many persons had pyothorax.

Dr. FLINT, Sr., had practiced the method mentioned in Dr. Rochester's paper in a number of instances.

Wednesday's Proceedings.

Sectional Work.—Dr. GOULEY reported that the question of dividing the meeting into sections had been considered by the special committee, which, while it had drafted a plan, was not prepared to present it for action at the present time. The number of papers was so great, however, that it indicated the necessity of a division into at least two sections at future meetings.

The Association's Library.—Dr. GOULEY offered certain resolutions looking to the establishment of a library for the Association, which should be as a city home for members when they visited New York. The resolutions were adopted.

In behalf of the Association, the PRESIDENT accepted of an original copy of the Code of Ethics of the American Medical Association, presented by Dr. Smith, of Philadelphia.

On motion of Dr. CARROLL, presented by the Secretary, it was voted that members of the Association might append to their names, in medical publications, the initials F. S. M. A.

Diarrhea resulting from Disease of the Pancreas was the title of a paper read by Dr. C. S. ALLEN. The author gave the history of a case of diarrhea in an aged river-captain, the stools containing adipose matter *en masse*, and also covering the consistent part a quarter to an eighth of an inch in thickness. He had therefore called it adipose diarrhea. Before having a passage, the patient suffered from pain in the region of the umbilicus. The pain ceased after the stool. There were three or four movements daily. There was no fever, the extremities were cold, the pulse was irregular, the urine was of a dark color and variable in quantity, and the muscles were flabby. The prognosis was considered unfavorable. The treatment had consisted principally in the administration of pepsin, pancreatin, opium, ipecac, and camphor. After some days the patient was able to go out, the diopse matter disappeared from his stools, and the pain ceased. Some weeks later the patient became comatose, but a few ounces of urine could be withdrawn from the bladder, and it contained a large amount of sugar and albumin, also casts and broken-down blood corpuscles. The patient died, but, unfortunately, an autopsy could not be obtained. The author cited from literature two cases of diarrhea resembling his case. It was supposed that they had resulted from disease of the pancreas.

The Address in Obstetrics and Gynecology was then read by Dr. T. GAILLARD THOMAS, of New York. [See page 561.]

At the opening of the afternoon session, a paper by Dr. B. L. HOVEY, of Monroe County, entitled "The Practice of Medicine Forty Years Ago, with Comparative Position at Present," was read by title.

On Venesection in the Convulsions of Pregnant and Parturient Women.—Dr. DARWIN COLVIN, of Wayne County, read a paper with this title, based upon his practice and that of his father, extending over a large number of years and including a great number of cases. It had always been his father's practice in puerperal convulsions, actual or threatened, to bleed the patient once or more, according to the urgency of the case. The author recited numerous cases in which all other means had failed except the abstraction of blood, varying in quantity at a single operation from sixteen to thirty ounces. The use of

chloroform had not been neglected. In no case had any unfavorable result followed venesection, and in no instance had a patient in their practice died from puerperal convulsions. His conclusions were: The physician should always see the patient two months before the expected delivery, and carefully examine the urine from time to time. If it contained much albumin, or the woman complained of headache or had oedema, venesection should be resorted to; she should be warned against all food likely to produce indigestion; the bowels should be kept in a free condition; if, toward the time of parturition, there was headache, oedema, or albuminuria, one should not hesitate to bleed; morphine might be a useful adjunct.

Dr. E. M. MOORE thought the paper should not be passed by without some discussion. Doubtless venesection in cases of convulsions during pregnancy would suspend this condition; it would also suspend neuralgia. During this suspension the woman could be delivered, there would be time for a cathartic to act, and it was the movement of the bowels which would cure the albuminuria or relieve the system of the poison. He preferred to gain time by suspension of the convulsions by the use of ether. Its administration should be kept up constantly even for a number of hours, until the cathartic had had time to act.

Dr. O. G. POMEROY agreed with Dr. Moore. He also knew of the beneficial action of venesection. He mentioned a marked instance in which convulsions were suspended a number of hours by the constant inhalation of chloroform, but returned when its administration was interrupted.

Dr. B. L. HOVEY related two cases of puerperal eclampsia, and said that he believed in all that Dr. Colvin and Dr. Moore had said, and yet he believed also that emptying the uterus was the essential and primary measure.

Dr. THAYER, of Brooklyn, directed attention to the use of veratrum viride in large doses, and said that, while the treatment was not new, he did not think it was so generally practiced as was desirable, or as was necessary to determine its exact value.

Dr. COLVIN said that in his cases he had employed cathartics and the other measures which had been mentioned, but the chief point to which he would have called attention seemed to have been overlooked, namely, the condition of the pulse, which he sought to make normal, and had so thoroughly succeeded in doing by venesection.

Dr. CROXON, of Buffalo, wished to thank Dr. Colvin much for having spoken in favor of the almost entirely neglected method of treating these cases by venesection. The cases in which the method had been employed by physicians of many years ago doubtless were of a similar kind to those which were treated at the present day by other measures, and he felt sure that much good had been accomplished by bloodletting and other measures mentioned this evening, including cathartics, but venesection had been of late largely replaced by other methods.

Fracture of the Base of the Acetabulum was the title of the next paper, read by Dr. C. C. F. GAY, of Erie County. [The paper will be published in full hereafter.]

The paper was discussed by Dr. COLVIN, Dr. CROXON, and Dr. BROWN, each of whom recited a case in which there had been doubt as to the diagnosis, there being some injury at the hip from a fall, but the paper read by Dr. Gay seemed to make it quite certain, they thought, that there must have been fracture of the base of the acetabulum.

A Case of Tubal Pregnancy of Fourteen Years' Standing, at Full Term; Autopsy.—Dr. J. G. ORTON, of Broome County, read the history of the case. The patient first consulted him in October, 1882, suffering from considerable pain in the region of the rectum. She had come from another State,

where she had gone through a long period of sickness, but she had regained her weight, health, and color. He found the uterus in place. By rectal examination he found, four inches above the anus, near Douglas's *cul-de-sac*, a hole half an inch in diameter; through this hole he felt a hard, movable body, and, on extracting it with the forceps, it was found to be the right tibia of a full-grown fœtus. A considerable amount of yellow oily fluid escaped. The next day he succeeded in removing a considerable portion of the spinal column, and on every other day for several days he continued to remove a portion of the bones. About one hundred in all were extracted in this manner. They were free of muscle and tendon. The hole in the rectal walls had been dilated to two inches. Her friends objected to anæsthesia, and the pain was too great to admit of removing all the bones at a single sitting. After a hundred of them had been removed, the patient was seized with an attack of severe diarrhœa, which, with her previous feeble health, resulted fatally in February, 1883. At the autopsy, ulcers and inflammation were found in the intestine, and the liver was fatty and somewhat broken down. On the right side of the median line, extending from the brim of the pelvis well down into Douglas's pouch, was a sacculated tumor, firmly adherent to the rectum, into which the rectal opening extended; it was attached to the intestines by recent peritoneal inflammation. The tumor consisted of the Fallopian tube, which was largely distended, but it in no wise involved the uterus or the ovaries. Within the tumor the remaining bones of the fœtus were found.

Dr. I. E. TAYLOR, of New York, referred to the case of a woman who died in Bellevue Hospital, immediately after he had been called to see her, and it was found that a hemorrhage had taken place from a vessel of the Fallopian tube, there being a tubal pregnancy of eight and a half months' duration. The specimen could be seen in the Wood Museum.

A Case of Tubal Pregnancy considered in Relation to Rupture of the Tube; Diagnosis and Treatment.—Dr. NATHAN BOZEMAN, of New York, then read a paper with this title. It will be published in full hereafter.

Dr. ARNOLD called attention to the fact that there was in the museum of the Albany Medical College a specimen of encysted fœtus which had been carried by a woman a great many years.

Dr. ROSS mentioned a case he had seen with Dr. Wey and two other gentlemen, in which the woman died about three months after the rupture of the sac of an extra-uterine pregnancy, and in which a very similar condition was found to that described by the author of the paper.

Dr. ROBERT NEWMAN, of New York, thought that tubal pregnancy was not so rare a condition as was generally supposed, and he thought Dr. Bozeman had done no more than justice in giving great praise to Dr. Rogers for the valuable suggestions which he had given the profession on this subject. Dr. Newman referred to a case or two of tubal pregnancy the histories of which had come to his knowledge.

After some further discussion with regard to the use of electricity in these cases, Dr. BOZEMAN referred to a case in which he lately had Dr. Rockwell apply electricity on four different occasions, with the apparent effect of killing the fœtus within the Fallopian tube. The history of the case, however, was not sufficiently complete to warrant its incorporation in the paper.

Dr. E. R. SQUIBB said there was a specimen of extra-uterine pregnancy in the museum of the Jefferson Medical College, the cyst having been carried by a negress probably as long as twenty years.

Hydrochlorate of Cocaine as an Anæsthetic in Ophthalmic Surgery.—Dr. C. S. BULL, of New York, read a paper on this subject. He directed attention to the recent introduction of the drug as an anæsthetic in operations upon the eye, and

divided his remarks into those relating to experiments as to the anæsthetic effects of the drug on the cornea and those regarding its action on the conjunctiva; experiments on the pupils; and experiments on accommodation. 1. The effects of the drug in producing anæsthesia of the cornea and conjunctiva were complete and positive. 2. The indirect effect of cocaine was much slower than that of atropine, and disappeared more rapidly. 3. The action on the accommodation was, to his mind, still unsettled, but he could say that the range of accommodation was shortened. The effect was less decided and more transient upon the ciliary muscle than upon the iris. In no case was complete paralysis of accommodation produced. He believed the drug was absorbed into the deeper tissues, allowing of operations upon them, but the effect here was slower and less marked than upon the cornea. Numerous illustrative cases of the foregoing points were given.

Dr. MITCHELL, of Rensselaer County, thought that in hydrochlorate of cocaine he had an anæsthetic which was of the greatest value, especially to the ophthalmologist. The value of such an agent in the treatment of diseases of the eye, in children particularly, could not be overestimated. He had previously been in the habit of using in these cases the bromide of ethyl, which had given great satisfaction, and in the small quantity required it had never done any harm.

Dr. E. R. SQUIBB had received a letter from Dr. Noyes before the one which Dr. Noyes had sent to the "Medical Record" had been published, and he immediately sent some of the hydrochlorate of cocaine to Dr. Bull and another gentleman. Dr. Bull was probably the first man in this city to employ it to produce anæsthesia of the cornea. Dr. Squibb then stated that it was very difficult to manufacture the drug, that all that was for sale in this country had been obtained from Europe, and that druggists had been unable to get a sufficient supply from any source since its anæsthetic properties had been made known to the profession. He was at present at work trying to make it. At best, it was rather dear, but at the price formerly demanded by the European manufacturers it was cheaper than ether as an anæsthetic in operations upon the eye, as so small a quantity was required.

Report of a Case of Dislocation of the First Phalanx of the Thumb forward.—In the evening session, Dr. FREDERICK W. PUTNAM, of Broome County, read a paper with this title, in which he gave the details of an ingenious method of reduction by manipulation which he had made use of.

Insanity: Preventive Measures.—This was the title of the next paper, read by Dr. JOHN P. GRAY, of Oneida County. The paper was largely a strenuous appeal for an energetic enforcement of like preventive measures in the case of insanity as were daily carried into effect by boards of health in regard to bodily diseases; for, in view of the grave nature of mental disease, the reader considered its prevention equally important to the community as that of the diseases against which sanitary regulations were now directed. Attention was pointedly directed to the close relation between bodily and mental health, and to the consequent necessity of taking all pains to so direct the physical as well as the mental training of the young as to give them the best attainable vigor of development. Among the most important anticipatory measures was the early recognition of the condition of the brain and nerves. In cases of depression we must recognize the absolute necessity of restoring and sustaining the energies by rest and nutritious food. Instead of advising travel and varied scenes, etc., attention should be directed to the use of narcotics and hypnotics to quiet the system. Patients were more or less sleepless, with varying appetite, and were not inclined to social life and amusement. The treatment was generally that which would give comfort and sleep. This class of

remedies, we must admit, while giving temporary comfort, at the same time were very apt to disorder nutrition and assimilation to such a degree as to cause more harm than good in the end. The prevention here came in, in resisting the plea for sedatives, and substituting food and rest. There were few practitioners who could not recall instances in which mistaken treatment, or no treatment, had carried the patient into hypochondria and melancholia. Many such cases had resulted unexpectedly, both to the physician and to the family, in acute mania. Illustrative cases were then cited by the reader.

A paper entitled "Cerebral Epilepsy," by Dr. C. F. MACDONALD, of Cayuga County, was then read by title.

Excision of the Knee in preference to Amputation in certain Deformities of the Leg.—Dr. STEPHEN SMITH, of New York, read a paper with this title. There was a certain class of cases, he said, in which the question of excision at the knee, or amputation at or below that point, was to be determined. They were those cases in which the leg was rendered useless for locomotion; closely allied to those cases of deformity and displacement in which there was chronic inflammation, and the weight of the body could not be borne on the limb. The solution of the question would depend upon two points: the comparative safety of the two operations and the comparative usefulness of a stump after an amputation at the knee joint, and at a point immediately above or below that point. Out of fourteen cases of partial excision, but two patients died, which was a mortality of only two per cent. Amputation at the knee joint for chronic affections, according to the latest authorities, gave a mortality of twenty-two per cent., showing a difference of eight per cent. in favor of excision. In a large collection of cases, amputation below the knee gave a mortality of thirty-four per cent., and amputation above the knee a mortality of sixty-three per cent. Although these figures showed that excision was by far the less dangerous, for purposes of comparison he would place them on the same footing. Perhaps the greatest weight of authority on the question had been furnished by the late Dr. Hudson, of this city, who was employed by the Government for several years. Much as he favored artificial limbs, he always regarded an ankylosed knee as more serviceable than a stump to which an artificial limb might be adjusted. In the light of these facts, we might formulate conclusions in regard to these operations as follows: That excision at the knee joint was quite as safe as amputation above or below that joint; that excision of the knee joint was to be preferred to amputation, by which the leg was rendered useless.

Dr. S. W. GROSS, of Philadelphia, took it that excision of the knee joint was not the proper operation in all cases of deformity of the knee; for instance, in cases of ossification or synostosis of the joint he saw no necessity of resorting to excision at all. In such cases it had been his practice, and that of his father, the late Professor Samuel D. Gross, to make an incision across the knee, and break up the osseous union with a chisel. Then the patella could be separated from its adhesion to the femur by force applied to it through a towel interposed. Then, on account of the danger of rupturing the popliteal artery, it was not safe to attempt to straighten the limb entirely at once, but it was best to bring the foot down only so far as was necessary to make the toes touch the floor—the heel, he thought, should swing about an inch above the floor. Even this it was safer to accomplish gradually, at several operations, the patient being anesthetized each time. This operation, he thought, should be more widely practiced in preference to excision, as had been taught by the late Professor Gross, in his "Surgery." In regard to the statistics brought forward by the reader of the paper, he would say that they had been materially changed within the last five or six years, and no surgeon who resorted

to antiseptic precautions would expect to have a mortality of more than three or four per cent. after amputation of the leg.

Dr. E. M. MOORE, of Rochester, had, perhaps, had an unusual timidity with reference to any operation upon the bone of the thigh. He felt that he had been too timid in this matter, and a case had presented itself to him last year, of the kind that Dr. Gross spoke of, in which the ankylosis was perfect. He used an osteoclast of his own construction, after the pattern of Robin's, fracturing the femur about three inches above the knee, and the patient made a perfectly good recovery.

The Curette; its Place and its Power in Uterine Therapeutics was the title of the next paper, read by Dr. GEORGE T. HARRISON, of New York. It will be published in full hereafter.

The Relations between Tuberculous Joint Disease and General Tuberculosis.—Dr. FREDERICK S. DENNIS then read a paper on this subject. It will be published in full hereafter.

Dr. GROSS ventured to say that no more important paper than this one would be read before the Association. Its importance was in regard to the early treatment of persons affected with tuberculosis of the joints. He fancied that every one was pretty well assured that primary articular tuberculosis was identical, anatomically and clinically, with primary tuberculosis of the lungs or of any tissue of the body. Not only did tuberculosis give rise to pyæmia, but it behaved very much like some of the other affections of its class. Strictly, primary tuberculosis was a local affection, but it soon extended. In addition to this, we found it behaved like carcinoma in affecting the lymphatic glands, and still more in giving rise to secondary foci and secondary conditions. This being the case, if we resorted to early operations, no matter what form of operation we might perform, he had no doubt we should succeed in saving many patients from the danger of acute miliary tuberculosis. He had some knowledge of the literature of tubercle of the joints, and he thought that the relations between primary and general tuberculosis were very well shown by the cases of death which occurred. Statistics were then cited from Billroth and other writers in support of the views advanced. In regard to treatment, if we laid the affected joint freely open, then with gouges cleaned out all foci, and thoroughly sprinkled the parts with iodoform, we should certainly prevent the formation of tubercle elsewhere in the body, and thus save many lives and limbs. He was quite sure, as Dr. Dennis had shown, in his case of extirpation of glands, that he had prevented dissemination of the disease.

On the Management of Breech Cases in which Both Extremities are reflected upward parallel to the Anterior Surface of the Child was the title of the next paper, read by Dr. WILLIAM T. LUSK, of New York. It will be published in full hereafter.

Women as Midwives.—Dr. THOMAS H. MANLEY, of New York, read a paper with this title. It was a forcible presentation of the well-known views entertained by Dr. Manley on this subject. It devolved upon the profession to provide some adequate means of medical attendance for the poor women of the community. Statistics were cited that had been furnished him by Dr. Nagle, of the Health Department of New York, which went to enforce the need of which he had spoken.

Thursday's Proceedings.

The Report of the Committee on Necrology.—At the morning session, Dr. S. S. PURPLE, of New York, presented the report of the Committee on Necrology, embodying appropriate resolutions in regard to the death of Dr. John G. Adams. The report was accepted, and the resolutions were passed unanimously.

Recent Gifts to Medical Colleges.—Dr. FLINT, Sr., offered the following:

Whereas The New York State Medical Association has heard with great gratification of the recent gift, by Mr. Andrew Carnegie, of fifty thousand dollars, for the erection of a building to be devoted to physiological and pathological laboratories, and of the more recent gift, by Mr. William H. Vanderbilt, of half a million dollars for the promotion of scientific research and instruction in medicine;

Resolved, That the Association tender to Mr. Carnegie and Mr. Vanderbilt congratulations and thanks in behalf of the interests of medical science and of humanity. Carried.

Officers for the Ensuing Year.—The Nominating Committee reported the following list of officers for the coming year: President, Dr. JOHN P. GRAY; Vice-Presidents, Dr. WILLIAM H. ROBB, Dr. J. G. OBTON, Dr. JOSEPH O. GREEN, and Dr. JOSEPH C. HUTCHINSON; Members of the Council for their respective districts, Dr. WILLIAM GILLIS, Dr. R. C. McEWEN, Dr. FREDERICK HYDE, Dr. DARWIN COVILN, and Dr. J. W. S. GOULEY; Secretary, Dr. CALEB GREEN; Treasurer, Dr. JOHN H. HINTON. The report was unanimously adopted.

A recess of five minutes was then taken, for the nomination of executive committees for the several districts.

An Address on Medicinal and Non-medicinal Therapeutics was then read by Dr. ARSTIN FLINT, Sr. It will be published in full hereafter.

A Resolution of Regret was then offered by Dr. FLINT, Sr., that, on account of the illness of Dr. LEWIS A. SAYRE, the members would be deprived of the pleasure of witnessing his demonstration of surgical dressings; and that the sincere sympathy of the Association be tendered Dr. Sayre in his prolonged illness, with an expression of the hope that he might soon be restored to health. Carried unanimously.

A Vote of Thanks.—The SECRETARIES said that he knew the Association was opposed in general to resolutions of thanks, but he felt that all the members would doubtless heartily favor a vote of thanks to Dr. J. W. S. GOULEY for his indefatigable efforts in organizing the Association. Carried unanimously.

Remarks by the President-elect.—After some further announcements by the Committee of Arrangements, the PRESIDENT introduced the President-elect, Dr. GRAY, of Utica, who said that he considered the compliment and honor bestowed upon him to be the highest that he could receive at the hands of his fellows, and he gave them his hearty thanks. The New York State Medical Association was not an offshoot from anything; it was not as a limb broken off from a tree; it was an original and a grand conception, projected into the present as a great necessity for the advance and progress of medicine. The members were men who simply believed in the declaration of principles that underlay the necessary organization of such bodies, as expressed in what was called the Code.

False Albuminuria was the title of the first paper at the afternoon session, read by Dr. GASPAR GRISWOLD, of New York. It will be published in full hereafter.

The following-named papers were then read by title: "Stretching of the Nasal and Infra-orbital Nerves in Ciliary Neuralgia," by Dr. C. E. ROSS, of Chemung County; "A Case of Ovarian Cyst, with Operation," by Dr. T. M. LLOYD, of Kings County; "Organic Disease of the Brain not a Constant Factor in Insanity," by Dr. SIMEON T. CLARK, of Niagara County; "Supporting the Perineum in the Act of Parturition," by Dr. JACOB HARTMANN, of New York; and "Report of a Gunshot Wound of the Stomach—Recovery," by Dr. JOHN H. HINTON, of New York.

The Early Use of the Knife in Nævus of the Cavernous Angioma Variety as contrasted with other Modes of Opera-

tion for Removal was the title of a paper read by Dr. SAMUEL W. SMITH, of New York. The author urged a more general use of the knife, as no other method was so useful in producing immediate good results. He used the term angiomatic nævus without particularizing as to whether the venous or the arterial element prevailed. He had seldom met with a case in which the knife could not be used, and he related the histories of two cases in which he had removed an angioma before it had attained to a great size. In the first case, the tumor was situated on the face, and had been treated elsewhere by methods which endangered life more or less. The result of the operation with the knife was complete success. In the other case the tumor grew from the lip of a child three months old, and that too had been treated without avail by other methods.

Abscess of the Liver was the title of the next paper, read by Dr. E. G. JANEWAY, of New York. It will be published in full hereafter.

Dr. ROCHESTER thought that the author had treated of the subject so exhaustively that it would be superfluous to add any further remarks, but he regretted that the time allowed him had not enabled Dr. Janeway to take up the subject of treatment, and he hoped that he would do so at no distant time.

Diphtheritic Croup was the title of the next paper, read by Dr. J. LEWIS SMITH, of New York. It will be published in full hereafter.

Dr. JOHN P. GARRISH, of New York, remarked that he had recently used bichloride of mercury, in very small doses, with great benefit in cases of croup.

Dr. ROCHESTER said that all physicians had tried various measures in the treatment of croup with more or less success. Recently his attention had been called to iodoform, and, in the case of a strong girl, eight years old, suffering with diphtheria with croupy symptoms, he had applied iodoform in powder, half an ounce to an ounce of bismuth, by insufflation, and the case had done well. Another child in the same family had previously died of the disease. In another case the iodoform had been applied undiluted, and had not caused irritation.

Dr. WILLIAM W. REESE, of Brooklyn, had applied common kerosene to the throat, on a flannel cloth, in cases of diphtheria during the past fifteen years, and, while he had seen severe cases, none had proved fatal when this mode of treatment was adopted. The oil caused irritation of the surface to which it was applied, but he thought that the benefit was largely due to its inhalation.

Dr. CARROLL said that the danger in diphtheria was not always commensurate with the extent of the exudation, malignant cases being an exception. He mentioned a case in which scarlet fever developed after the patient had recovered from diphtheria of nine days' duration. The patient died of the scarlet fever.

Dr. MOORE said that the point made by Dr. Rochester, the necessity of a persistent use of whatever agent was used, was an important one. He then gave his experience with the bicarbonate of sodium, in fine powder, continuously employed by means of the Davidson syringe connected with a glass tube inserted through the stopper of a bottle containing the alkali, a second tube giving exit to the powder. This was constantly blown into the face and throat, notwithstanding the patient's cries. Sulphur burnt in the room at the same time would prove of benefit, and after a while would not be irritating to the occupants of the room.

Typical Cases of Diabetes not before reported was the title of the next paper, read by Dr. ARSTIN FLINT, Jr., of New York. [See page 569.]

Dr. S. S. CLARK, of St. Albans, Vt., related his experience of the influence of dietetics in his own case. It had resulted in

a considerable reduction in his weight—in a few weeks he fell from 215 pounds to below 210. The amount of sugar in the urine also diminished, but there was likewise a marked decrease in the specific gravity of the secretion, to as low as 1.008, but still he was able to detect the presence of a small amount of sugar. The strict diet caused weakness and a general failure of health, so that on several occasions he had felt compelled to go back to a diet containing farinaceous matters.

Dr. FLINT said, in reply to a question, that about 1.010 was the lowest specific gravity of the urine in which he had been able to detect sugar in any of his cases.

Dr. FRIEDEL related the history of the case of his only son, who, shortly after being bitten by a prize-fighting dog, was noticed to have sugar in the urine, and died, in spite of all treatment, including a faithful trial of dietary. The literature of the subject showed the great difficulty, if not the impossibility, of controlling diabetes in the young.

Rupture of the Uterus.—Dr. Ross presented a specimen, and read the history of the case, which had occurred in the practice of Dr. Woodward, of Vermont. The patient was known to have deformity of the pelvis, but had been ten times pregnant, and had been delivered at term. In her last pregnancy she refused to be delivered prematurely, as had been advised by Dr. Woodward, and sent for him (the speaker), when she was taken in labor at term, but death occurred within ten minutes after his arrival, before there was time for any interference. The post-mortem examination showed a full-grown fetus, with all the membranes, in the peritoneal cavity, into which they had escaped through a large rupture in the posterior wall of the uterus.

A Case of Conservative Surgery, and Results.—Dr. R. B. BONTÉCOR, of Troy, showed a man upon whom he had performed a secondary operation after gunshot injury of the shoulder joint, with a very good result. The power of motion which now existed at the shoulder was due to movement of the scapula, the joint itself being ankylosed. The deltoid was atrophied.

Report of a Case of Ligature of the Primitive Iliac Artery for Diffuse Aneurysm of the External Iliac Artery.—This was the title of a paper read by Dr. J. W. S. GOULEY, of New York. It will be published in full hereafter. At the close of his paper, Dr. Gouley referred to a case in which a soldier, in 1864, suffered a penetrating sword-wound of the brachial artery, high up. The treatment of such a case—by ligature above and below the wound—illustrated the management of what might be called an embryo aneurysm.

Dr. FRIEDEL referred to the teachings of John Bell, and remarked that, in his work on "Surgery," would be found an excellent description of modern surgery, even including the practice of antiseptic surgery.

Dr. MOORE related a case of traumatic aneurysm of the brachial artery in which he tried the treatment adopted by Dr. Gouley in the case last reported by him, and in which, as it was impossible to put a ligature above and below, he had the vessel compressed above by the thumb of an assistant. But the assistant's thumb slipped after the sac had been opened, and most terrible hæmorrhage followed, which, however, was finally controlled by pressure with towels. He afterward, with great difficulty, succeeded in tying the vessel below the clavicle, but subsequently hæmorrhage took place under the ligature, and proved fatal.

The paper was further discussed by Dr. C. B. NANCORDE, of Philadelphia.

This ended the formal proceedings. On Thursday evening the Association was entertained at supper at the Murray Hill Hotel by the Fellows residing in New York County. On Friday

morning surgical operations were performed, and demonstrations given, by Dr. FREDERIC S. DENNIS, at Bellevue Hospital, after which the Fellows took part in an excursion to the hospitals and other institutions on the islands in the East River.

CLINICAL SOCIETY OF THE

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Meeting of November 8, 1884.

Dr. D. B. ST. JOHN ROOSA in the chair.

Hydrochlorate of Cocaine.—Dr. T. E. SATTERTHWAITE opened the discussion of the evening by a paper upon this subject, and added the remark that the subject before the society was one peculiarly appropriate for its consideration from the fact that the name of one of its members must be connected with the history of the drug. He referred to Dr. W. O. MOORE, who was the first to operate, in this country, using the cocaine as an anæsthetic, thus demonstrating its practical value.

The CHAIRMAN stated that he operated every day in the week, using cocaine for anæsthesia. He had to-day removed a soft cataract in a child of ten or twelve years, and had operated for strabismus in a still younger one without pain.

Dr. MOORE considered cocaine cheaper than ether for operations upon the eye; he said that two drachms of the solution, costing \$1.50, would do for ten or twelve operations, while ether would cost from eighty cents to one dollar for each. He had noted the pallor of the conjunctiva after the use of the cocaine, also some paræsthesia of the external surface of the lid.

Dr. J. B. EMERSON said that his experience with hydrochlorate of cocaine had been somewhat limited. He had used it in slitting up the canaliculus and in passing probes in cases of lachrymal obstruction; also in cutting the internal rectus in cases of squint; and in every case had succeeded in rendering the parts sufficiently anæsthetized for all practical purposes. He had tried the drug with four cases of chronic catarrhal conjunctivitis, where the conjunctiva was much thickened and infiltrated. The result in each case had been decided diminution of redness. He had also tried it in two cases of burn of the conjunctiva from lime. Not only did it relieve the intense pain, and render the removal of the lime easy, but it also diminished the redness. He had tried it in three cases of vascular keratitis, with the result of contracting the blood-vessels on the conjunctiva, while their continuation on the cornea was unaffected. He had used it in several cases of foreign bodies in the eye, with the result that the conjunctival hyperæmia was decidedly diminished. There was no doubt in his mind that hydrochlorate of cocaine acted on the vaso-motor nerves and diminished the blood supply, and he could only explain its non-action on the blood-vessels in the cornea by the supposition that the new-formed vessels had no muscular coat, while those of the conjunctiva had. If this was true, another field was open for the use of the drug, viz., in all sthenic inflammations of the eye, in which it could act the double part of relieving pain and reducing inflammation. And it would be contra-indicated in those troubles which were of an asthenic character, such as ulcers of the cornea from inanition, &c. Of course, this must be determined by clinical observation.

He had tried the drug on the unbroken skin with negative results; but, on removing the epidermis and applying it, complete anæsthesia was produced, but only so far as the epidermis was removed. It was evident that it was necessary for the drug to be absorbed, and that absorption could not take place to any extent through the epidermis. He had had still less experience

with its use in aural disease; but, as the external layer of the membrana tympani was a continuation of the epithelium of the auditory canal, it would stand to reason that, in cases of aural disease where the membrana tympani was attacked, there would be little or no effect so far as relieving pain was concerned; and in acute cases, as a rule, the pain ceased when the drum broke. What its effect would be in reducing inflammations of the tympanum where the membrana tympani was gone, remained for the future to show. This he knew, that where granulations were to be removed, or a sensitive ear was to be cleaned, it could be done, without pain to the patient, by the use of this drug.

Dr. F. C. RILEY had had no effect from the drug in a case of intense pannus, though he had applied the solution six or seven times, using three or four drops each time. He had also had a failure in a case of perforating ulcer of the eardrum. Apparently the drug was not absorbed.

Dr. LEZYSKY had assisted Dr. Agnew when performing an iridectomy, the iris being adherent to the cornea, and in an operation for strabismus, without pain. He had tried it in an enucleation, by injection upon the muscles after the division of the conjunctiva, but had been obliged to resort to ether.

Dr. GEORGE J. BALL said that when a two-per-cent. solution of the hydrochlorate of cocaine was applied to the inflamed conjunctiva it was evident, from the immediate blanching of the surface, and from the diminished caliber of the blood-vessels, that the drug exerted an important influence through the vaso-motor nerves. This was further shown by the blanching of other mucous surfaces, and by the lessened hæmorrhage following operations in which cocaine had been employed. It therefore became a question whether the new anæsthetic might not impair nutrition in certain operations in which the slightest impairment might affect the result injuriously. In two cases of cataract extraction in which cocaine was employed the operations had been followed by sloughing of the flap. It might be well to consider whether this was more than a mere coincidence.

Dr. GEORGE B. HOPE had during the past week tested the value of cocaine in the removal of a papilloma of the larynx. The case in many respects was a particularly difficult one. The growth was attached to the lower free margin of the vocal cord, very near the anterior commissure, and, except during forced phonation of the lower tones, remained quite hidden from view. To add to the difficulty, the type of it was hard and very much arched, and the parts about the pharynx and soft palate were thickened and irritable. When the patient was first seen, nearly three months ago, his voice was completely lost, although his respirations were not at all troubled beyond a constant though slight cough, and his general health was good. The growth was of about the size of a pea, with quite a broad pedicle. For a time the efficacy of training with a sound was tried, to see what could be accomplished to subdue the irritation; but, as little or nothing was gained, his attention was turned to the removal with laryngeal forceps. It was impossible to see the forceps in place beyond the tip of the epiglottis, and immediately a suffocating spasm would ensue that made it necessary to manipulate quickly and at great disadvantage. The consequence was that, up to the latest trial, not more than a third of the growth had been removed. In the application of the cocaine in this case, the larynx, epiglottis, pharynx, and soft palate were thoroughly painted with a four-per-cent. solution, and, after waiting a few minutes, it was found that the forceps could be guided well into the larynx without producing any spasm. At the first attempt a larger portion was removed than at all the previous sittings combined. While in this case the larynx and epiglottis were made insensible to the presence of the instru-

ments, the pharynx and soft palate preserved in a measure, their reflex irritability, due, it might be, to the excessive flow and tenacious character of the saliva, preventing the absorption of the drug or washing it away before it could properly take effect.

Referring to the subjective symptoms, the taste was extremely bitter and a little irritating; a sense of decided coldness of the upper air-passages quickly took place; the respirations were free and prolonged, and accompanied by an agreeable sensation of exhilaration; the flow of saliva at first was largely increased, and then the secretion became tenacious and afterward normal. No pain occurred when the tissue was torn away, there was very little immediate or subsequent irritation, and the vocal cords were well under the patient's control. Twenty minims of a four-per-cent. solution, or two thirds of a grain, were used in the case.

Dr. W. C. PHILLIPS said that, as the amount of hæmorrhage varied so much in different individuals subjected to the operation for the removal of hypertrophied tonsils, he determined to make a test-case in a patient who offered the opportunity of a double tonsillotomy. He used the hydrochlorate of cocaine on one side only, applying a two-per-cent. solution, by means of a curved probe covered with cotton, to the left or larger tonsil the left half of the pharynx, and all the tissues that might come in contact with the instrument. After the incision he noticed:

1. That no hæmorrhage occurred for a few seconds, and that it was at no time profuse.
2. That there was very little sensation of choking on the part of the patient.
3. That the cut surface was more than ordinarily anæmic in appearance.

The right or smaller tonsil was afterward incised in the usual way without recourse to anæsthesia, and more choking was noticed, the hæmorrhage was more profuse and instantaneous, and the cut surface of the tonsil was redder than on the other side.

If other operations verified this result we might conclude that the uses of the hydrochlorate of cocaine in cases requiring excision were:

1. To lessen the hæmorrhage.
2. To do away with the choking sensation.
3. To relieve the pain caused by the operation.

He also reported a case of sensitive throat where he was able to make a thorough examination with the laryngeal mirror after the drug had been applied—a thing utterly impossible before.

Removal of a Papilloma of the Larynx under Local Anæsthesia by Hydrochlorate of Cocaine.—Dr. ANDREW H. SMITH reported the following case:

"Mrs. N., aged sixty-five, widow of a clergyman, was referred to me by Dr. A. E. M. Purdy, with a papillomatous growth, of twice the size of a coffee-bean, depending from the anterior commissure of the vocal cords. Aphonia had existed for fifteen years, and of late there had been severe dyspnoea on the least exertion. The growth could be easily seen with the laryngoscope. Its attachment was narrow, and the mass hanging down in the larynx, causing but little inconvenience so long as the breathing was tranquil. But, the moment the respiration was hurried or forced, the growth was forced up between the cords, and occupied the greater part of the area of the rima glottidis. The dyspnoea was then extreme, and the patient often felt as if she would 'lose her breath entirely.'

"Several attempts were made to seize the growth with forceps, and a small piece was removed in this way. But the spasmodic closure of the glottis with each approach of the instrument made it extremely difficult to get below the cords. A snare was then arranged in such a way that the loop would pass be-

tween the cords in a direction parallel to them, but would turn half round in being withdrawn. By this means it was hoped that the growth would be encircled by the loop, as the latter came up crosswise through the rima. But the firm closure of the glottis prevented the rotation of the loop until it had passed the lower end of the growth, and the plan was a failure.

"Meantime I had secured some of a two-per-cent. solution of the new anæsthetic, and on November 12th I pencilled the larynx with it three or four times at intervals of two or three minutes, and then used it for a few seconds in the form of spray. The mucous membrane was then seen to be whitened, as if by the use of a weak solution of silver nitrate. I was now able to introduce a loop of wire crosswise between the cords and for a distance of more than half an inch below them, and to carry it up to the neck of the tumor, the cords remaining motionless. On drawing the wire home, the growth was readily separated from its attachment, and brought away entire. It was found to measure five eighths of an inch in length and one fourth of an inch in diameter. A very moderate hæmorrhage followed the removal, and the difficulty of breathing was at once relieved.

"It would be difficult to imagine anything more satisfactory than the effect of the cocaine in this case."

Dr. W. K. SIMPSON had also used a two-per-cent. solution, preparatory to making laryngeal examinations, with good effect. A "freezing and choking" sensation was complained of in some cases.

Dr. A. H. SMITH also reported Dr. Shaw as having used it in removing a toe-nail. He had wrapped the toe for a few minutes in cotton saturated with the solution, had then divided the nail and removed it, without pain.

Dr. M. J. ROBERTS reported that Dr. Eddy, a dentist, had used it with success in cutting operations upon the gums, but had not found it of any benefit when applied in sensitive teeth.

Dr. C. A. VON RAMDOHR had succeeded in making an examination in a case of vaginismus, which had always before resisted every attempt, by brushing the mucous membrane with some of the solution.

Dr. SENECA D. POWELL reported a case of deep urethral stricture where the sensitiveness was so great that the introduction of even the softest instrument, without anæsthesia, was impossible. He had been in the habit of using nitrous-oxide gas, but, having obtained some of the cocaine, had injected it by means of a small syringe and catheter, and had then found no difficulty in passing a steel sound. After four dilatations using the cocaine, the irritability had so far disappeared that anæsthesia of any kind was no longer required.

Dr. H. G. LITTLE also reported a case of internal urethrotomy in a patient, aged twenty-two, who had suffered from a gleet for fourteen months, following urethritis, and due to strictures of large caliber. He found three strictures—one at the meatus, one at two inches and a half, and the third at four inches and a half, which admitted No. 10, No. 22, and No. 23 F. bulbous sounds, respectively. The normal caliber of the urethra was 33 F., according to Otis. The meatus had been cut to admit a 33 F., but had recontracted to 28 F. The urethra was moderately sensitive. Previous to the operation a two-per-cent. solution was injected by means of a No. 12 F. gum catheter with a rubber bulb attached. Fifteen drops of the solution were then introduced beyond the deepest stricture and the bulb was compressed. Some of the solution came out at the meatus, and the catheter was withdrawn. This was repeated three times at intervals of five minutes. The first introduction of the catheter caused some pain, the second very little, and the last none at all. The penis became quite small, cold, and anæmic, especially the glans. Otis's urethrotome was introduced, five minutes after the last injection, for five inches, and screwed up to 35 F.,

and the guarded blade was withdrawn. The patient complained of severe pain while the strictures were being put on the stretch, but of none at all when they were cut. He afterward stated that the pain was deep down in the canal, and the doctor thought that it was due to the fact that the drug was not injected deep enough. In his next case he would use a soft rubber catheter and introduce it down to the prostatic urethra, whether operating on the deep urethra or not. No unpleasant after-effects were noticed from the use of the drug.

Dr. C. S. BENEDET had used the hydrochlorate of cocaine in three cases with marked benefit:

"CASE I.—Male, aged forty-two, was operated on five months ago, for stricture, by external urethrotomy. Every passage of a steel sound since had been accompanied by so much pain and constitutional disturbance as to unfit him for labor for the ensuing twenty-four hours. On Monday last I passed a 30 F. steel sound, having previously injected twenty minims of a two-per-cent. solution of the hydrochlorate of cocaine by means of a soft rubber catheter. There was absolutely no pain and there were no disagreeable after-results from the operation.

"CASE II.—A piece of iron firmly imbedded in the conjunctiva caused so much pain as to seriously interfere with examination. It was removed without the patient's knowledge after two instillations, of five drops each, of the two-per-cent. solution of the hydrochlorate of cocaine, at intervals of four minutes. The patient spoke voluntarily of the astringent action of the anæsthetic.

"CASE III.—A splinter of wood, 2 cm. in length, was left in the ball of the thumb after repeated domestic attempts at removal, and the broken skin permitted an application of the two-per-cent. solution to the deeper tissues. The necessary incision was then made without pain and with trifling hæmorrhage."

PHILADELPHIA CLINICAL SOCIETY.

Meeting of October 24, 1884.

Dr. BEATES in the chair; Dr. G. BETTON MASSEY Secretary.

Extra-uterine Pregnancy; Rupture; Peritonitis; Recovery.—Dr. E. E. MONTGOMERY read the following history of a case:

"Mrs. M. has had four children and two miscarriages, the last miscarriage occurring some four months since. She has for several years suffered from chronic phthisis. Menstruation was absent for two periods, but two weeks ago she had a bloody discharge for several days. Although she had been suffering from the phenomena usual to her in early pregnancy, she then concluded that she was not pregnant. On the 18th of March, after a fright, she was taken with severe pain in the right side, which, continuing to grow worse, was attended by frequent micturition, a sensation in the pelvis of weight or bearing down, intermittent vomiting, and a serous vaginal discharge. Her husband called at 8 A. M. to-day (the 19th), informed me she had cramps, and asked for a prescription for her relief. I gave a prescription containing an eighth of a grain of sulphate of morphine to each dose, to be given every two hours until relief took place.

"I saw her at 8 A. M., when she was quite pale, complaining still of pain in the right inguinal region. As I had a clinic at 9 A. M., I made a hurried visit, injected a quarter of a grain of morphine hypodermically, and ordered a pill of two grains of sulphate of quinine and half a grain of opium every three hours.

"5 P. M. Pain somewhat relieved; stomach very irritable; would retain nothing; pain greatly increased by vomiting; face pinched, pale, and anxious-looking; lips bloodless; pulse 90. Bimanual examination disclosed the uterus slightly enlarged and retroverted. Douglas's *cul-de-sac* presented a mushy or doughy

sensation; on the right side could be felt a small, irregular-sized mass, which was diagnosed to be an escaped fetus, from a tubal pregnancy. The pills were discontinued, and a grain of extract of opium, in suppository, ordered to be given every six hours, and an alkaline mixture of $\frac{f}{3}$ ss. each of milk and lime-water were given every three hours, by the stomach.

"20th.—She slept poorly, but does not suffer so much from pain. There is marked tenderness over the lower part of the abdomen, more marked upon the left side. On examination *per vaginam*, the mass is felt posterior to the uterus, and is quite hard and tender upon pressure. The uterus is fixed; pulse 90; vomited once. She has been kept perfectly quiet; the bladder relieved by the catheter. Ordered five grains of sulphate of quinine and a grain and a half of extract of opium, in suppository, every six hours.

"21st.—General condition better, though she slept but little. The introduction of the suppositories was attended with so much pain that they were discontinued, and a sixth of a grain of sulphate of morphine, with two grains of sulphate of quinine, was given every three hours, by the mouth.

"22d.—Some sickness of the stomach; pulse 88, temperature normal; very nervous, easily disturbed. Abdomen still tender to pressure. Returned to the use of the suppositories. Slept well last night after twenty-five drops of deodorized tincture of opium were given.

"24th.—Temperature normal. Pulse 80. Abdomen still tender, especially over the lower portion and left side; movement attended with pain. The suppositories induced so much pain that they were discontinued, and thirty drops of deodorized tincture of opium were given by the mouth every three hours.

"Subsequent to this date the convalescence was gradual. She regained her strength very slowly. She left the city the latter part of July, returning about the middle of September, again pregnant. Upon examination, a few days ago, the uterus was found enlarged to the usual size at two months, and posterior to it could be felt a smaller mass, in which the remains of the former gestation were evidently encapsulated.

"In such cases it becomes an important question to decide when we should proceed to surgical measures. Notwithstanding the successful termination of this case, I would not uphold the treatment as the one most likely to yield a favorable result. Had the symptoms of shock and internal hæmorrhage persisted during the third day, as upon the second, it was intended to make an abdominal incision, remove the fetus and effused blood, and ligate the bleeding vessels. Such a course, pursued with the advent of the characteristic symptoms, would, without doubt, decrease the mortality of the accident."

Extra-uterine Pregnancy successfully treated with Electricity.—Dr. Montgomery related also the following history of a case furnished by Dr. JAMES SIBBALD, of Wisahickon:

"Mrs. R., aged thirty-four years, a woman weighing one hundred and seven pounds, of spare build and exceedingly nervous temperament, was married when twenty-one years of age, and had a miscarriage about five months subsequently, since which time (for thirteen years) she was never pregnant, although very desirous of becoming so. Her menstrual periods were always regular and natural up to June 16, 1884, at which time there was no sign of menstruation. One week later she commenced feeling sick in the morning, and also complained of soreness, with decided tenderness on pressure, over the right inguinal region, which gradually increased in severity. At the same time bloody discharges would appear, with no regularity, every week or two, lasting from a few hours to several days.

"On July 3d, while standing in the street dealing with her butcher, she was suddenly seized with a violent pain in the ab-

domen, which caused her to fall in the street. She was picked up and carried to her bed. Morphine was administered hypodermically, and poultices were applied for six days before the tenderness subsided. For the next three weeks there was more or less tenderness over the right inguinal region.

"On August 4th (just one month after the first attack) she had a second attack of local peritonitis, which lasted five days. At this time she was sweeping the floor, when she suddenly fell, overcome by the severe abdominal pain.

"After the acute symptoms of the first attack had subsided, a vaginal examination revealed a soft mass on the right side of the uterus, very sensitive to pressure, and displacing that organ to the left. The sound was passed cautiously into the uterus a distance of over four inches without obstruction. These facts, in connection with the cessation of menses, morning sickness, some enlargement and soreness of the breasts, with occasional bloody discharges from the uterus, warranted a diagnosis of extra-uterine pregnancy.

"On August 18th Dr. Montgomery saw the case in consultation, and coincided in the diagnosis. He advised the destruction of the fetus, which was now in about the eleventh week of gestation, by means of electricity. Eight applications of the battery were made, which had the desired result. The mass is slightly perceptible on examination at the present time, the womb being still displaced on the left side. Menstruation has returned twice since, being perfectly normal, and no inconvenience is now experienced."

Dr. JOHN B. ROBERTS coincided with Dr. Montgomery as to the advisability of performing laparotomy where the symptoms of rupture continued urgent.

Dr. CLARA BARTON asked what form of electricity had been used.

Dr. G. BETTON MASSEY said that the question put by Dr. Barton was of no little importance, and that the answer should depend on a clear conception of the work to be done in a given case. Electricity was employed for two separate and distinct purposes in extra-uterine pregnancy: to kill the fetus, and to produce its absorption. In the former case, a somatic death of the germ contained in the tumor was desired; in the latter merely a molecular death or change. In this latter instance, where the death of the fetus had occurred and we merely wished to promote its absorption, together with that of any effused blood or other material, the indications were almost exactly similar to those in any other intra-abdominal tumor; the current of the greatest electrolytic power—the galvanic—was to be preferred. On the other hand, if we wished to arrest the onward progress of life in the fetal mass, in the interest of the unfortunate mother, that current was to be preferred which would accomplish this object with least danger to the mother. This undoubtedly was the faradaic current. Shock must be the quality of value here. It was simply a question of transmitting a sufficiency of shock through the abdominal wall of the mother to the more vital parts of the fetus. If the ordinary faradaic battery was not strong enough, the gravity of these sad cases would even warrant the building of a weak dynamo for the special purpose. As to the method of application: the external, percutaneous passage of the current by moistened electrodes would seem to be the best. A vaginal electrode might be used, however, the principal endeavor being to send the current directly through the tumor. Dr. Thomas and Dr. Mundé had recently reported a number of cases to the American Gynecological Society, in which successful results had followed the use of electricity. To Dr. Massey's mind, however, their remarks, as reported, lacked definiteness in this matter of the choice of current and as to the exact object aimed at in the individual cases. Dr. Thomas did not advise the use of electricity after

the fifth month, but an operation instead. Possibly he anticipated a speedy, then a probable death, but this could be overcome by increasing the strength of the current in the manner he had indicated. Even if an operation was afterwards performed, the previous arrest of the placental circulation might be of value.

In response to inquiries by Dr. Hall and Dr. Roberts, Dr. Massey said that an insulated sound with a free extremity would form an excellent vaginal electrode, but that the necessary puncturing of the cervix was wholly unnecessary.

Dr. MONTGOMERY said that he had applied one electrode in the vagina, in contact with the uterus, and the other over the hypogastrium. He thought acupuncture unnecessary, although it was formerly the practice to use it, as it was liable to cause perforations from the liquor amnii escaping into the peritoneal cavity. There was but little to choose between the two currents. There were two reasons why electricity was not available after four months and a half or five months. The difficulty to rupture was greatest in the early months, before the third month. After that, we might as well allow the case to go on to a later month, as an operation would be necessary. A large fetus was more dangerous to the mother after the loss of its vitality, and could not be allowed to remain. Although the woman had fallen, in the case related, he thought the fetus was still living, and therefore advised the electricity with the direct purpose of killing it. Subsequently the tumor became smaller. The fetus and appendages became encapsulated in the abdominal cavity in these cases. There was no advantage in destroying the fetus prior to an operation.

CHICAGO MEDICAL SOCIETY.

Meeting of November 10, 1884.

The President, Dr. D. A. K. STEELE, in the chair;

Dr. LISTON H. MONTGOMERY, Secretary.

Two Cases of Gastrostomy. Dr. EDWARD ANDREWS opened his *Report on Surgery* with the histories of these cases. In his introductory remarks he criticised the word gastrostomy as of defective formation; to express the idea of a "stomach-mouth-cutting" fully, we should have to say *gastrostomotomy*.

The first case was that of a little girl, aged six years, who swallowed some concentrated lye several months before she came under the writer's care. The liquid cauterized the lower part of the œsophagus and gradually induced a stricture. Dr. E. P. Cook, of Mendota, Ill., had previously dilated the stricture, and sent the child home greatly improved; but, after leaving his care, she relaxed. When she came under the author's observation she had been unable to swallow anything for a number of days. Dilatation was essayed, and improvement followed for a time with partial power of swallowing liquid food. However, the advantage gained could not be maintained, and, after faithful trial, it became evident that the patient was gradually starving. Gastrostomy was performed in a room which had been sprayed for an hour with carbolic acid, but the spray was not allowed to touch the peritoneum. The operation consisted in making the usual incision in the hypochondrium from near the xiphoid cartilage downward and to the patient's left. The operator found the colon partly in the way, but, pushing it downward, he drew out the stomach with long toothed forceps, identified the viscus by the relations of the gastro-epiploic vein, and secured it to the abdominal wall by a long suture on each side. The stomach was opened freely, and its edges were sewed close to the skin *all around* the incision. There was a good deal of shock, but reaction occurred and union by first intention took place without difficulty, and with no peritonitis.

Reperforated food was carefully inspected, and, on inspection, found perfectly digested, except when meat was used. This, whether raw or cooked, was ejected from the wound unchanged even when retained several hours. For some days the patient improved, but it soon became evident that most of the food, though digested, did not pass through the pylorus. It seemed that this orifice of the stomach required a little pressure to unfold it, and that, whenever the stomach contracted for the purpose, the chyme escaped by the fistula into the dressings and did not pass on into the intestines. A rubber pad tight enough to stop the outflow could not be tolerated, and a soft rubber tube and valve, having a thick circular flange at one end an inch and a quarter in diameter, was provided. The introduction of this valve against the inner wall of the stomach, and clamping the tube outside, prevented leakage. This valve-like device produced no perceptible irritation of the walls of the stomach; the food was retained perfectly and the patient took an abundance of it, and she would call for her meals. This improvement was but temporary, and she began to fail slowly without obvious cause. The power of assimilation seemed gone, and the little patient constantly grew weaker. At the thirty-fifth day after the operation it was perceptible that the end of her life was near, and the last twenty-four hours were accompanied with an obscure fever. The second case was that of an adult male. Six months ago he swallowed some caustic ammonia, producing a contracting ulcer of the lower part of the œsophagus. In September last he placed himself under the writer's care, having been unable to swallow anything for some days. By a diligent use of bougies, the stricture was dilated sufficiently to restore the power of swallowing liquid food. He then returned home, having learned the art of passing the bougie himself, and taking two instruments of different sizes with him. However, he lost the art in some way, and in October returned again in the same condition as before. Repeated trials at dilating the stricture a second time gained nothing permanent, and but a slight temporary power of passing small quantities of liquids a day or two at a time. On the whole, his progress was downward and he was slowly starving, and, aside from this, the points of the bougies seemed to be creating a local inflammation in the right lung, as if they were making a false passage in that direction. Their further use was discontinued, and the same operation was performed as in the first case, except that the opening was smaller. The same difficulty of regurgitation of the food occurred and was controlled by a similar valve. The patient was now doing well, thirty-two days since the operation, and seemed likely to recover.

The plan pursued by Mr. Howse, of London, and those of other surgeons, all of which were quite identical, were then described, also their advantages and disadvantages commented on at length. Dr. Andrews thought that perhaps, on the whole, the mechanical parts of the operation should be something after Howse's plan, and then at the same operation a moderate meal of milk and raw egg should be inserted through a small aspirator tube. Considerable space was allotted to the statistics of this operation, which were not very promising. Of two hundred and seven cases recorded, forty were for cicatricial stricture of the œsophagus, like those just instanced. Of these forty, twenty-one had ended fatally. Still, when patients had no other hope of life, an operation which gave them one chance in two was a great benefit.

Two Cases of Excision of the Rectum were next related in the report. The first case was one of epithelioma. As the disease did not reach down to the verge of the anus, the entire external sphincter was saved. The incision was carried from an inch in front of the anus back to the coccyx, opening the anus antero-posteriorly and cutting off the gut just above the

verge. After dissecting it upward a little and tying numerous vessels, the rectum was separated from the pelvic chamber, mainly by the finger, and divided about three inches up, just above the top of the cancer. There was no shock and not much subsequent pain or inflammation.

The second case was almost exactly like the first, except that the verge of the anus was involved in the disease, and, consequently, was dissected out with the rest.

The patients were doing well, but it was too early to state whether there would be any return of the disease.

Litholapaxy was the next topic discussed in the report. Dr. Andrews had operated by this method twenty-three times with only one death. His plan consisted in keeping the nerves of the bladder benumbed during the operation by filling the organ with carbolized water, which tended powerfully to prevent both shock and inflammation. It was worthy of inquiry whether the remarkable local anæsthetic properties of the new agent, hydrochlorate of cocaine, would not enable us to operate without ether and without shock.

A New Varicocele Clamp, devised by the reader, was shown, and the report concluded with its description and with some general remarks on the operation of curtailing the scrotum. This clamp held the scrotum so that it could not slip while the section was made, and yet it did not compress it so as to interfere with the proper treatment of the arteries.

It consisted of two curved steel parallel bows connected at the ends and inclosing a slot three eighths of an inch wide between them. Twelve holes were drilled through the bars, of a size to admit ordinary pins. The surgeon drew the scrotum through the slot to such a distance as he deemed sufficient, and secured it there by inserting as many pins as were necessary. He then cut off that part of the scrotum outside the convex border of the bars. As the scrotum was not pinched by the instrument, the blood spouted freely, especially from the artery at the raphé, and the operator could carefully and deliberately secure every bleeding point. This being accomplished, he sewed the cut edges together, and then, drawing out the pins, removed the bow and applied his plasters. The neatness and dispatch of the operation were thus greatly enhanced.

Political Abuse of the Insane.—In a paper with this title, Dr. S. V. CLEVINGER alluded to a number of instances of abuse of patients in lunatic asylums, and dwelt, in particular, upon the difficulties that Dr. Kiernan, the superintendent of the Cook County Asylum, was meeting with in his attempts to put an end to the abuses which had flourished under political rule.

The secretary having read a letter from the Citizens' Association, requesting the appointment of a number of physicians to act with them in investigating the charges of mismanagement at the asylum, the President appointed Dr. C. G. Smith, Dr. E. F. Ingals, Dr. C. G. Paoli, Dr. R. Tilley, and Dr. C. W. Earle—the Citizens' Association to select three of the five mentioned.

The Shan-Tung Dispensary and Hospital, at P'ang-Chia-Chuang.—The fourth annual report of this institution, prepared by Dr. HENRY D. PORTEE, who was for a number of years a missionary physician in China, was read by Dr. JOHN H. CHEW.

National Sanitation.—The committee appointed at the meeting of September 15th (consisting of Dr. O. C. DE WOLF,

chairman, Dr. R. E. STARKWEATHER, Dr. L. H. MONTGOMERY, Dr. JOHN BARTLETT, Dr. J. H. ETHERIDGE, Dr. A. R. JACKSON, and Dr. J. H. HOLLISTER) presented a report embodying the following preambles and resolutions:

"Whereas, Experience has firmly established the fact that the ravages of certain infectious and contagious diseases may be in great measure prevented, restricted, controlled, or arrested by the enforcement of suitable sanitary regulations; and

"Whereas, The United States is constantly exposed to the importation of disease from foreign countries, and subject, because of the facility and rapidity of inter-state transit to the rapid spread of infection once finding lodgment on our borders; and

"Whereas, This exposure, because of the prevalence of cholera in Europe, is just now unusually great; and

"Whereas, The facts are that matters of sanitation are in some of the States of this Union entirely neglected, while in others they are simply taken cognizance of by the appointments of boards of health in their functions advisory only, and unclothed, not vested, with powers of authoritative action; and

"Whereas, Either of these State boards of health, as now constituted, may prove derelict or inefficient in its duties, or act without concert with, or even in antagonism to, the boards of other States; and

"Whereas, The exigencies occasioned by the appearance of violent epidemics demand organized means for the prompt recognition of the outbreak of disease, and vested authority, limited in its area by the boundaries of the country only, to take such immediate steps in matters of protection, as vaccination, isolation, quarantine, etc., as experience has taught to be useful; and

"Whereas, No national authority in sanitary matters now exists; therefore

Resolved, That it is the judgment of the Chicago Medical Society that the sanitary interests of the United States demand the establishment of a permanent national health authority, which shall have for its main functions the detection of pestilential and epidemic diseases, and the enforcement, where necessary, of sanitary regulations tending to prevent, to abate, or to suppress them.

Resolved, That, as a step toward the consummation of the idea suggested in the foregoing resolution, a committee of three be appointed by this society to collate facts tending to show the usefulness and necessity of a national sanitary organization, and to compile the same in such form as may be available for disseminating information upon, and creating an interest in, national sanitary legislation.

Resolved, That the said committee be empowered and instructed to urge the importance of national legislation upon the attention of the congressional delegation from Illinois, and fittingly to present the subject to the representatives of the people in both houses of Congress."

The resolutions were carried, and Dr. JOHN BARTLETT, Dr. RALPH STARKWEATHER, and Dr. JOHN H. HOLLISTER were appointed members of the committee.

Hydrochlorate of Cocaine.—Dr. BOERNE BETTMAN read a paper on this subject. Hardly two months had passed, he said, since the introduction of this drug as a local anæsthetic, and already current literature teemed with instances of its successful employment. His brother and himself had experimented in order to ascertain its physiological effects.

Two drops of a four-per-cent. solution applied to the left eye of Dr. J. Bettman produced in a few minutes a feeling of slight stiffness. In two minutes complete anæsthesia set in, permitting the manipulation of the cornea with a brush and probe without causing the slightest pain. Sensibility began to return after ten minutes, and was perfectly restored in fifteen minutes. In sixteen minutes the pupil showed a slight dilatation. In two hours it was of medium size. Repeated applications of the drug produced more pronounced and lasting effects. Four drops induced a maximum dilatation in fifteen minutes, and not until eighteen hours afterward did the pupil assume its normal size. Reaction to light in the anæsthetized condition was

prompt. The action of cocaine on the essayist's eye was similar to what had been recounted. Insensibility to touch had disappeared in five minutes. Ten minutes later the pupil was dilated. Distant vision remained the same. The accommodation was decidedly influenced, the near point having receded from 4 inches to 12. Snellen 0.5 was read at four inches with the aid of + 14. The mydriasis was complete in half an hour. The benumbing effects of the drug now began to disappear, and passed away entirely in three quarters of an hour. The dilatation of the pupil lasted eight hours. The outer surface of the right eye was rendered insensible to the pricking of a pin.

CASE I.—Oloff D., aged twenty-two, consulted the writer for a stricture of the nasal duct. A few drops of a four-per-cent. solution of cocaine produced complete anesthesia in three minutes. A Weber's knife was introduced into the canaliculus and thrust forward into the sac, and the duct was slit open with but trifling pain to the patient. With an Anel's syringe a few drops were injected into the nose. Five minutes later the firm stricture was forced with a Bowman's probe. The pain, according to the patient's statement, was remarkably less than that experienced five years before from a similar operation. The anesthesia lasted fifteen minutes.

CASE II.—A piece of steel had been imbedded in the cornea of a policeman for two days. The eye was extremely sensitive. Two drops of the solution benumbed the eye in three minutes. The digging out of the mote with a spud was painless.

CASE III.—Mr. M. complained of severe earache produced by an otitis media acuta purulenta. The introduction of a cotton-holder or speculum was not permitted. Instillation of two drops of the solution was followed by almost immediate cessation of pain, when the ear could be manipulated without the slightest annoyance to the patient.

CASE IV.—The most striking results were obtained in the case of Mrs. T. A cataract operation was performed on the right eye. Several drops of the solution, applied every few minutes, produced complete anesthesia in ten minutes. The corneal section was made without the patient being aware of the fact. The only step in the operation which caused the slightest pain was excision of the iris. At this stage, when questioned about the sensation, she remarked it felt as if a pin were pricking her. She expressed herself highly pleased with the action of the drug, assuring the operator repeatedly that, with the exception of the slight pricking pain, she had felt absolutely nothing of the entire operation. The wound had healed nicely, and her sight was good.

The physiological and therapeutical effects of the remedy might be epitomized as follows: 1. It was a powerful local anæsthetic, not penetrating in nature, rapid in its effects, which, however, were only temporary. 2. It was a mydriatic to a degree determined by the strength of the solution. 3. It produced paralysis of the ciliary muscle, the near point receding from the eye, and distant vision not being influenced. 4. By virtue of its benumbing powers, it might be classified as an anodyne.

Hydrochlorate of Cocaine in Nasal Surgery.—Dr. JEFFERSON BETTMAN related a case of "asthma nervosum," and gave illustrations of the applicability of cocaine in nasal surgery. Its action on the nasal mucous membrane, as had already been demonstrated by Knapp and Gruening, was similar to that on the eye. Only within a very short time had it been possible to obtain even a small quantity of this drug in Chicago, so that his experience had been limited to the following case:

Dr. K., a physician of this city, had been under treatment, suffering from asthma nervosum. The asthma was purely reflex, induced by great hypertrophy of both inferior turbinated bones. Excepting an occasional obstruction to free nasal respiration, but little discomfort was experienced during the day. A recumbent posture and the warmth of the bed were sufficient to produce a reflex turgescence of the lower turbinated bones. A subsequent serous discharge took place, and, to complete the clinical picture, a culminating violent attack of asthma. The nares were extraordinarily sensitive. The introduction of any

instrument into the nose was exquisitely painful. Previous treatment had consisted in applications of the galvanic cautery to reduce the volume of the erectile tissue in the nose. The abnormal sensitiveness, however, would only permit of superficial cauterizations, so that the results obtained were but partially successful. On the 8th of the present month it was resolved to apply the hydrochlorate of cocaine prior to cauterization. A pledget of cotton of sufficient size was soaked with fifteen drops of a four-per-cent. solution and placed in the inferior meatus of the left nostril. At the expiration of ten minutes the parts were perfectly anesthetized. At the end of a quarter of an hour the plug was removed and the parts were thoroughly cauterized with a sharp-cutting electrode. The application exceeded three seconds in duration, and produced but a minimum degree of pain. In fact, the discomfort was so trifling that the patient cheerfully submitted to a second vigorous application at the same sitting. After a period of twenty-five minutes the sensibility of the parts was fully restored. The action of the white heat was so thorough that its ultimate results would probably eclipse the benefit derived from previous more superficial application of the cautery.

BUFFALO MEDICAL AND SURGICAL ASSOCIATION.

Meeting of October 7, 1884.

The President, Dr. F. W. BARTLETT, in the chair.

Tuberculosis of Bone.—Dr. ROSWELL PARK showed some bones which illustrated two phases of tuberculosis. The first specimen consisted of three dorsal vertebrae now firmly welded together, not in their normal relationship, yet happily illustrating a natural cure of that destructive spinal caries which we must regard as a local tuberculous process. It showed that recovery might follow a local tuberculosis, sometimes spontaneously, often with judicious aid from the surgeon.

The other specimen consisted of the three bones of an arm which Dr. Park had amputated at the shoulder joint on account of most extensive disorganization of the shoulder, elbow, and wrist joints caused by a tubercular osteitis and osteomyelitis following typhoid fever. In different places evidences would be seen of various pathological processes, some destructive, some reparative. At the articular ends especially cavities were to be seen, formed by local foci, some of which had ulcerated toward or into the joint, while others had perforated outside the joint capsule, causing periarthritic abscesses and sinuses.

One object he had in showing these specimens was, that he might substantiate the position he took with regard to the frequency and pathological importance of local tubercular processes, not merely in bone, but in nearly every tissue in the body. He had recently been subjected to semi-public criticism because he accepted heartily the view of this subject taken by every pathologist on the Continent of Europe, and those present had been warned that these views were directly opposed to those held by many English and American surgeons, and that therefore they were to be rejected. Passing over in silence the phenomenal ignorance of the critic, he would consider the facts. There certainly was a wide difference of opinion between English and Continental teaching on this subject. Those who simply read English books, and observed but little, fell in at once with English views. But those who not only were familiar with Continental literature, but saw many cases and operated frequently, or made many autopsies, held with remarkable unanimity to contrary opinions. The average practitioner, who perhaps saw from time to time an occasional joint affection of a class among which the typical "white swelling" was most prominent, might be satisfied to accept the English dictum, as pronounced by Barwell, that in nearly all of these cases the

trouble began in the synovial membrane. But the careful student, who insisted on going back as nearly as might be to prime causes, who studied carefully the history of his cases, who was a competent microscopist, who made careful sections of bone, and who had examined many museum specimens, soon came to the conclusion that the large proportion of these cases began by foci of irritation and inflammation in the articular ends of the long bones, and that the evident joint lesion, which was of such objective relative significance, was, after all, not the primary but the secondary disturbance. This view was held by every surgeon and pathologist of note on the Continent to-day. More than this, those ideas had not even the attractiveness of novelty, for they were clearly enunciated nearly fifty years ago by Nélaton, while since that period they had at no time dropped into obscurity, but had been more and more fully stated by him and by his numerous students and followers, who had accumulated sufficient proof, ante-mortem and post-mortem, upon which to base their statements; so that now hardly a general surgical principle could be thought of which the speaker considered more firmly grounded.

If, now, he were asked why English and American authors were oblivious of these truths, the answer was a difficult one. Perhaps it might be got from the reply made to him by Dr. H. H. Smith, of Philadelphia, when he recently asked him the same question. He said: "Doctor, these men don't know anything about it, and, what is worse, they don't want to learn." Dr. Smith, by the way, was the pioneer in these studies in this country, and it was his address on this very topic at the meeting of the American Medical Association in this city, in 1878, which first aroused Dr. Park's own interest in the subject. To it and to the illustrations accompanying it he would gladly refer those who were interested in the subject.

But time failed in which to give even a brief discussion of the subject, for it was an exceedingly broad one and had by itself a literature already extensive, emanating from authorities too eminent to be ignored or disbelieved. Volkmann, whom the speaker esteemed the best living authority in this matter, had written much thereon, and his contribution to the new "Deutsche Chirurgie" was to be looked for with great interest. Every one of the other German surgeons whose names were daily in our mouths was in the closest accord with him. To him König, of Göttingen, had dedicated his recent monograph on "Tuberculosis of Bones and Joints." Recent publications by Mögling, Schreiber, and many other German students contained the same sentiments. Prominent among the French stood Ollier, of Lyons, with all the noted surgeons of the French capital in full agreement. The beautifully illustrated work of Launelouge was a fitting addition to Nélaton's original brochure, and more recent contributions by Menard and Charvot admirably continued the subject into the present year.

But where in our own literature should we look for a suitable exposition of the subject? In no text-book that he knew of. An occasional journal article placed some individual on record in a creditable way. Gibney's admirable little work on "Hip-Joint Disease" furnished an excellent exposition of the true pathology of tubercular disease of a single joint, though by the nature of the work the discussion had to be limited, but it stamped him as an advanced pathologist as well as orthopædist.

The pernicious doctrine of the traumatic origin of chronic joint disease had unduly influenced the average professional mind, in which a pathological problem was never harbored, and, as a consequence, the effect of the general constitutional condition and of the inherited predisposition (diathesis) was overlooked. So it happened that the accidental cause—the injury—was given the chief rôle, and the tuberculous diathesis was made

to play a subordinate part or entirely overlooked. Why teachings of this kind were given a high place at home, and the facts accumulated in every Continental museum and in a rich foreign literature were ignored, was a question to which no satisfactory answer could be given. It was a fact for which no sufficient excuse could be alleged. We had reached a period when operative and mechanical surgery was carried to the extreme, and the fundamental principles of surgical pathology were almost ignored. It was making progress by the base of the triangle and not by its apex.

Reports on the Progress of Medicine.

OPHTHALMOLOGY.

By CHARLES STEDMAN BULL, M. D.,

LECTURER ON OPHTHALMOLOGY AND OTOTOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE; SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; OPHTHALMIC SURGEON TO ST. MARY'S FREE HOSPITAL FOR CHILDREN AND TO THE NURSERY AND CHILD'S HOSPITAL.

Antiseptics in Ophthalmology, especially Mercuric Sublimite; and Cauterization of the Cornea.—Sattler (Bericht der ophth. Gesellschaft: "Beilageheft der kl. Mon. für Augenheilk.," 1883) has been investigating the subject of antiseptics usually employed in ophthalmic surgery, with special reference to whether they suffice to render the effect of germs innocuous within a short space of time, such as from one to five minutes. He thinks that in the sterilized blood-serum brought to the consistency of jelly we possess an admirable productive soil in which to carry on the culture-experiments at the temperature of a hatching oven. Sattler has convinced himself by numerous experiments that by no means all, not even the most, of the germs which are capable of development, when inoculated upon the cornea of animals, are able to take root, germinate, and produce a purulent keratitis; and this is especially true of the spores of various kinds of bacilli. This has been proved to be true also of the mold-fungi and of the cleft-fungi. In his experiments he at first employed as germs the micrococci from purulent dacryocystitis, and later the jequirity bacilli, as they always produced a conjunctivitis, and when inoculated in the cornea, gave rise to an hypopyum-keratitis. Thin silk-fibers, sterilized by heat, were saturated with the pus-micrococci or jequirity-bacilli dried and then placed for from four to twenty-four hours in shallow bowls, which were filled with the various antiseptic solutions. Here they lay from one to five minutes, and were then rapidly washed out with boiled distilled water, placed upon the culture gelatin, protected from the atmosphere and observed at blood temperature. These experiments showed that, among all antiseptics hitherto employed, chlorine-water held the first rank, as it sterilized the germs within one minute. Next in value to the chlorine-water was the mercuric sublimite in solutions of 1 per mill, or 0.5 per mill., which are, however, too strong to use on the conjunctiva, though very useful for disinfection of the surrounding skin, hands, sponges, and instruments. A solution of 0.2 per mill. sufficed in three minutes to sterilize the germs. Weaker solutions, however, proved very uncertain in their effects. Next in value came resorcin and hydrochinon in three-per-cent. solutions, which in about three minutes cause all action to cease in the germs. Concentrated aqueous solutions of salicylic acid also proved very useful, as well as a solution of salicylic and boric acids, but the application of the latter to the eye is painful and its preparation somewhat difficult. Solutions of carbolic acid stand in about the same category. Boric acid, on the contrary, proved of very slight value, even when of concentrated strength. The peroxide of

hydrogen, recommended by Landolt, also proved of but little value, and absolute alcohol proved entirely useless in destroying dried germs. The older the impregnated threads are before being brought in contact with the antiseptic solutions, the more easily are the germs destroyed or neutralized. Before operating, Sattler recommends that the hands of the operator and of his assistants, and the skin of the patient's face in the vicinity of the eye, should be disinfected with a solution of mercuric sublimate, one to a thousand. Then the conjunctival *cul-de-sac* should be disinfected with a sublimate solution, 0.2 to the thousand, which does not irritate the eye. In cases where suppuration had already started, and hypopyum was present, he recommends, in addition, either a moistened sublimate bandage, or frequent applications of sublimate cloths, upon the eye. In some cases he employed powdered iodoform. If all these means fail, he recommends cauterization of the wound by the galvanocautery. The battery he employs is a Grenet's element of moderate size, and the current can be broken with the greatest ease. The eyelids are held apart with the fingers or elevators, and the end of the platinum cautery is applied easily and carefully to the desired spot, without fixing the eyeball or using any anæsthetic.

The Mode of Origin of Myopia.—Förster (*Ibid.*) considers briefly the two hypotheses of tension and convergence offered in explanation of the origin of myopia. If the tension hypothesis is correct, then spasm of the tensor muscle is to be avoided, concave glasses are to be cast aside, and when they are used it is always at the expense of the healthy condition of the eyes. If the convergence hypothesis is correct, the convergence of the axes must be diminished as far as possible; concave glasses then become indispensable in limiting the growth of myopia. The fact that the misuse of too strong concave glasses is not injurious to the eyes works against the tension hypothesis and somewhat in favor of the convergence hypothesis. Should all these cases of myopia not become progressive, is it because the over-correcting glasses caused these patients to fix at a greater distance, and thus effected a diminution in the convergence of the axes? If the diminution of the myopia always depends on a neutralization of the spasm of accommodation, it would follow that this spasm is a secondary symptom, caused by the marked convergence employed by myopes in their work. Thus, in the development of myopia we meet with a *circulus vitiosus*, the first link in the chain being a faulty position of the body, which induces too large an angle of convergence. The extreme convergence first causes spastic myopia, which in its turn calls for a still greater degree of convergence, and thus is developed the real axial myopia. This *circulus vitiosus* can be broken by paralyzing the accommodation with atropine, or by increasing the reading distance by the use of glasses. The momentary success of the atropine treatment seems to indorse the tension hypothesis. Since, however, the cause of this—viz.: the axial convergence—is not done away with by the use of atropine, the spastic myopia continually recurs whenever the patients return to their original work.

A New Instrument for Tattooing the Cornea.—Parisotti ("Rec. d'ophth.," Jan., 1884) has invented a modification of Taylor's instrument for tattooing the cornea. It is composed of a rectangular hollow shank of hard rubber, resembling the fountain-pen. At one end of this shank is a bundle of needles, arranged in the same manner as in Taylor's instrument. At the other end is a rubber ball carrying a small metallic tube, which can be screwed into the upper end of the canal in the shank. The lower half of the surface of the ball rests in a metallic half-cup. The central canal of the shank is filled with a solution of India-ink before the operation. The needles are then pressed into the corneal leucoma, and, on withdrawing them, the thumb

must press upon the rubber ball at the top, which forces the India-ink into the holes made by the needles.

Ophthalmoscopic Examinations of the Insane.—Uthoff (Bericht d. ophth. Gesellschaft: "Beilageheft d. kl. Mon. f. Augenheilk.") here gives the results of his examination of a large number of patients suffering from the various forms of mental disease. The number of his examinations amounted to 542. Of these, 170 were cases of psychosis or functional mental disturbance; 150 were cases of progressive paralysis of the insane; 135 were cases of chronic alcoholism; 56 were epileptics, and 31 were cases of positive foci of disease of the brain or spinal cord. Among these last 31 cases there were 20 that showed symptoms of disease in the fundus, viz.: 8 cases of cloudiness of the retina or papilla with slight neuritis optica; 3 cases of choked disc; 3 cases of atrophy of the optic nerve; 1 case of extreme hyperæmia of the papilla in tubercular meningitis; 2 cases of retinal hemorrhage; 2 cases of hemianopsia; 1 case of conjugate deviation. Pupillary reaction was absent six times in these 31 cases: three times in *tabes dorsalis*, twice in *ophthalmoplegia externa*, and once in senile dementia. Among the 150 cases of progressive paralysis of the insane, 75 showed signs of ocular disease, the most frequent being a more or less intense opacity of the retina and disc, which extended far toward the periphery of the retina. Slight forms of actual neuritis optica were relatively rare (6 cases), and a real papillitis or choked disc was never seen. Next to the opacity of the retina and disc, the most frequent ophthalmoscopic symptom in progressive paralysis was atrophy of the optic nerve, of which there were 13 cases; in addition, there were 21 cases of abnormal discoloration of the papilla which could not be designated with certainty as atrophy. There were also three cases of marked hyperæmia of the papilla and one case of retinal hemorrhage. The reaction of the pupil to light was wanting in about half the cases of progressive paralysis. There did not seem to be any connection between this symptom and the presence of ophthalmoscopic changes. Among the 135 cases of alcoholism, 55 showed positive ophthalmoscopic changes, the most frequent being a diffuse cloudiness of the retina and papilla, with indistinctness in the outlines of the latter, but without much disturbance of the vision. The next most frequent change was a partial atrophic discoloration of the disc, limited usually to the temporal half. In two cases there was a slight neuritis. In five cases there was hyperæmia of the papilla. Among the 56 epileptics, 7 showed pathological changes in the fundus, 2 showed slight neuritis optica, 2 abnormal discoloration of the papilla, 1 hyperæmia of the papilla, and 2 slight cloudiness of the retina and papilla. Among the 170 cases of psychosis, 17 showed pathological changes in the fundus. Of these, 11 showed slight cloudiness of the retina and papilla, 3 were cases of discoloration of the papilla, 2 showed hyperæmia of the papilla, and 1 was a case of retinal hemorrhage.

Certain Changes in the Plica Semilunaris.—Eversbusch (*Ibid.*) calls attention to certain unusual conditions in the semilunar fold in man, among the rarest of which as a congenital anomaly is the presence of cartilaginous tissue. Another congenital anomaly includes the various forms of angiomas, the most common of which consists in enormous dilatation of the caliber of the vessels with simultaneous thickening and fibrous degeneration of their walls. The fibrillary structure of the plica is in places pressed aside and made to gape. Many of the blood-vessels are newly formed and surrounded by masses of small round cells, while others are older and only separated from each other by a very thin frame-work. Immediately beneath the epithelium the fine fibrous connective tissue is infiltrated with red-blood corpuscles. Acquired anomalies of the plica are excessively rare, except those due to inflammatory

changes in the conjunctiva. He reports two cases of hypertrophy or increase in volume of the plica, manifestly due to constitutional syphilis and probably consisting in a gummy infiltration of its tissue, though Eversbusch seems to think the trouble was a syphilitic papule.

A Peculiar Case of Persistent Hyaloid Artery and Coloboma of the Iris.—Eversbusch (*Ibid.*) reports a case of this kind in a child a few days old, with bilateral coloboma iridis downward. In the space of the coloboma was a white, triangular plug, which extended from the bottom of the coloboma to the lower periphery of the lens. Attached to both sides of this plug, and running backward toward the optic nerve, was a persistent hyaloid artery, still containing blood. On the death of the child the eyes were examined, and the plug was found to be intimately connected, not only with the lower margin of the lens and with the hyaloid artery, but with the sclera also. The similarity of the plug in histological structure to the normal sclera and its persistent connection with it render it probable that this was a persistence of the mesodermal process found in the earliest phases of embryonic life.

A Peculiar Form of Ophthalmomalacia.—Schmidt-Rimpler (*Ibid.*) discusses the nature and pathology of those cases of atrophy of the eyeball with simultaneous diminution of tension coming on in a healthy eye, and gives the results of the examination of such an eye removed from the body of a patient who had died suddenly from heart disease. Before death, attention had been attracted by the small size of the left eye, ptosis of the lid, and myosis, though the eye was apparently healthy. The vessels of the left auricle were dilated and the skin was livid. A few days before his death there was a transient paralysis of the right arm. At the autopsy there was found marked softening of the upper layers of the left optic thalamus. The left sympathetic was markedly pigmented, and small apoplectic extravasations were found between the ganglion-cells. A careful examination of the eyeballs and orbital contents showed a marked diminution in volume of the left eye. In a second case, of a woman who died of cerebral apoplexy, there was diminution in size of the left eye, loss of tension, ptosis, and myosis. At the autopsy there was a clot as large as a walnut in the right thalamus, extending into the corpus striatum, chronic inflammation of the pia mater, and serous effusion. The ptosis must not be attributed to a paralysis of Müller's muscle, for any diminution in size of the eyeball will cause a drooping of the upper lid.

The Presence of Caterpillar-Hairs in the Conjunctiva and Iris, together with the Formation of Tubercle-like Nodules.—Pagenstecher (*Ibid.*) reports a singular case of this kind in a female child, aged ten years. The ocular conjunctiva of the right eye was strewed with small nodules as large as a millet-seed. These nodules were dense, grayish-yellow, and freely movable; they occurred both in groups and isolated, and were numerous near the retro-tarsal fold. The iris was thrown into folds in the infero-nasal quadrant, and at the pupillary end of these folds were a number of similar grayish-yellow nodules. Under the microscope these nodules resembled tubercles, except that in the center of each nodule there was a caterpillar-hair. An iridectomy was then made, and the section of iris containing the nodules removed. These, on being examined, showed the same structure, and also the presence of the same animal-hair in the center of each nodule. It is supposed that a caterpillar crept into the child's eye, and that in brushing it out some of the hairs were driven into the conjunctiva, and even through the cornea. This origin seems, at the best, to be problematical.

Sarcoma of the Choroid surrounded by a Shell of True Bone.—Leber (*Ibid.*) reports a case of this kind, found in an eye which had been enucleated from a girl, aged eleven, on ac-

count of an intra-ocular tumor in a glaucomatous condition. The tumor was found in the posterior section of the choroid, was sarcomatous in character, and was of a marked cavernous structure. The bony capsule inclosing it was surrounded by fibrillary connective tissue. The origin of the ossification could not be traced to a previous plastic choroiditis, and hence we must assume here an actual, partially ossified sarcoma. The remaining choroid showed no special changes. There was, however, a shrunken cataract, with a space between capsule and lens, capsular cataract, and a peculiar variety of partial staphyloma at the sclero-corneal margin. There was no cause found for the development of the sarcomatous growth.

Xerosis of the Conjunctiva.—Leber (*Ibid.*) reports here some cases of xerosis conjunctiva, with abundant proliferation of the fissured fungi, in the desquamating epithelium. In one case, in a child, the whitish mass was easily removed from the eye, and was found to consist of epithelial scales which were covered with fungi, both round and rod-shaped. They existed in great numbers, and were also found in the corneal ulcers, in the interior of suppurating eyes, and also in the kidneys. He undertook to inoculate some of these spores in the conjunctival *cul-de-sac* of animals, and gained surprising results. The lids were kept closed for two days, and then opened, and it was found that a severe purulent keratitis had developed. A microscopical examination showed in the purulent infiltration in the cornea a number of groups of the fungi, of usual rosette-shape, and around them a zone of denser purulent infiltration.

The Ætiology of Ophthalmoblenorrhœa Neonatorum.—Zweifel ("Archiv für Gynäkologie," xxii, 2, 1883) reviews the literature of this subject, and publishes some observations and conclusions drawn from his own experience. He refers to Hecker's observations (same "Archives," xx, 3) as leading only to negative results in leaving the ætiology of ophthalmia neonatorum still more problematical than it should be. He admits that, although the relative rarity of the disease is in favor of there being a specific virus, yet it is not a certainty. It is certainly true that children have been born with healthy eyes of specifically diseased mothers, and the eyes have remained healthy. It can not be even approximately determined how many children escape the great danger of being infected. This fact, in connection with the very easy transmission of the inflammation of the eyes from one child to another, makes of but little significance every conclusion as to the specific character of the affection from the frequency of its occurrence. Hecker's opinions, based on observation of over eighteen thousand births, do not indorse the generally accepted view of the infection of the eyes by the vaginal secretion during birth. The highest percentage of conjunctival disease did not occur in long-protracted labors, but in those of the shortest periods, and Hecker thinks that the duration of the period of incubation from one and a half to six days does not necessarily demonstrate that the infection can only occur during birth. Admitting that infection may occur after birth, this must take place either by subsequent infection from the lochial discharge or by the contact of the secretion from the eyes of one child to those of another child. The most important question in the ætiology of the disease is, however, to decide whether the ophthalmia neonatorum is caused *solely* by infection with specific cocci, the diplococci of Neisser, or the gonococci; or whether the simple catarrhal vaginal secretion or the normal lochial discharge *can* also produce a purulent conjunctivitis. The probability of an identity of the virus in ophthalmia neonatorum with the virus of gonorrhœa has been demonstrated by the inoculation of the purulent secretion of the conjunctiva upon the urinary passages of adult men and women. In his experiments with the normal lochial secretion, Zweifel took the secretion from the vagina in a thoroughly clean pipette

and as rapidly as possible inoculated the conjunctival *cul-de-sac* of a child. A portion of the secretion was also examined microscopically, and there were found in it but very few cocci, and no gonococci at all. In the six cases in which this experiment was carried out, not a single case of purulent conjunctivitis occurred. The lochial secretion from the third to the thirtieth day was used, bloody, serous, and purulent being thus employed, but the result was always the same. As regards prophylaxis, Zweifel regards Credé's method as the best—that is, the instillation of a two-per-cent. solution of silver nitrate. This no doubt causes a superficial cauterization of the epithelium, but it does not injure the eyes.

Miscellany.

THERAPEUTICAL NOTES.

Alum in the Treatment of Intermittent Fever.—This remedy has lately been tried quite extensively in Russia, says the "Union médicale." Dr. Ignatieff, after a series of clinical experiments, rejects the drug as being far inferior to quinine. Dr. Pethoff, on the contrary, has been successful in several obstinate cases, in some of which quinine had produced no effect. Dr. Koltchewsky, whose experience with the new antipyretic has been large, states that, out of twenty cases which were carefully observed, the results were negative in all but two. The evidence in general goes to prove that alum is of doubtful value in intermittents.

Inunctions of Oil in Fever.—Colrat reports, in "Lyon médical," a series of observations on children. In a number of cases of scarlet fever, small-pox, and broncho-pneumonia he has found the temperature lowered as much as two degrees by the use of oil inunctions. The decline begins immediately after the inunction, the temperature remains stationary for two hours, and then begins to rise again. The younger the child, says the reporter, the more pronounced is the fall of temperature. He noticed that a child who was previously restless and irritable would fall asleep at once after being rubbed. No special directions are given as to the method to be followed.

The Antipyrine Rash.—Now that antipyrine is coming into more or less general use as an antipyretic, it may be interesting to state that several cases of an exanthematous eruption following its use have been observed in the clinics at Breslau, Zürich, and Strassburg, as reported by Cahn in the "Berliner klinische Wochenschrift." The eruption appeared, without any subjective symptoms, in the form of round, reddish, somewhat elevated spots, which disappeared on pressure. It was principally distributed over the back and the extensor surfaces; the head, the palms of the hands, and the soles of the feet were not affected. The eruption disappeared as soon as the use of the antipyrine was discontinued, but returned when it was resumed.

Hypodermic Injections of Calomel for Syphilis.—Julien ("Annales de dermatologie et de syphiligraphie") uses the following preparation:

Calomel.....	0.10-0.15 gramme;
Powdered gum arabic.....	0.05 "
Distilled water.....	1.00 "

This is the amount used at each injection. Two injections are given in the region of the nates, and no more are used until three weeks have elapsed, when two more are given. This constitutes the entire treatment. The results reported are most gratifying.

Chlorate of Potassium in the Treatment of Burns.—The "British Medical Journal" contains an article by Dr. J. W. Brown, suggesting the use of a lotion of chlorate of potassium (five grains to the ounce) in burns. It is applied on pieces of lint, and these are covered with oil-silk. The dressing should be changed at least four times a day. The writer speaks highly of this mode of treatment.

The Internal Administration of Salt in Uterine Hæmorrhage.—Betz, in the "Centralblatt für Gynäkologie," commends this remedy in emergencies in which transfusion is impracticable for any reason. He dissolves five grammes of salt in half a litre of hot water, and gives

three tablespoonfuls of the solution at intervals of five minutes. He cites a case in which this simple remedy proved efficacious, and states that its use is not accompanied by nausea.

The Treatment of Cold Abscesses with Injections of Iodoform.—Verneuil ("Revue de thérap. méd.-chir.") treats cold abscesses as follows: Having removed the pus by means of a Potain's aspirator, he injects into the cavity, with the same instrument, from fifteen to twenty grammes of iodoform dissolved in glycerin. If this amount is not exceeded, he states, there is no danger of poisoning. The solution fills all the depressions in the abscess cavity, and deposits a uniform layer of iodoform on the pyogenic membrane. This method of treatment is said to be perfectly safe, since there is no fear either of introducing septic germs or of setting up fresh inflammation, such as frequently follows the injection of tincture of iodine. The simplicity of the method renders it easy of application by one of no pretensions to surgical skill.

Esmarch's Escharotic Powder.—The "Union médicale du Canada" publishes Esmarch's formula for an escharotic powder as follows:

Arsenious acid.....	1 part.
Sulphate of morphine.....	1 part.
Calomel.....	8 parts.
Powdered gum arabic.....	48 parts.

To be applied to superficial growths, warts, etc., the surface having first been shaved off with a bistoury.

The Treatment of Albuminuria with Chloral.—Dr. Wilson states, in the "British Medical Journal," that he has treated a few cases of albuminuria with this drug, and has noticed that by its constant use he was able to cause a complete disappearance of albumin from the urine, the albumin reappearing as soon as the remedy was suspended. The theory of its action is not stated.

Salicylate of Sodium in Acute Cystitis.—Borgehold mentions, in the "Deutsche medicinische Wochenschrift," twenty cases of acute cystitis in which he produced good results by the internal administration of this drug. During the first three days of the treatment he gives half a gramme every two hours; for the succeeding eight days he gives the same quantity thrice daily. The writer asserts that with this method he is able to dispense entirely with irrigation of the bladder, and that in none of the cases thus treated has the disease become chronic.

Iodide of Potassium for Asthma.—The "Union médicale du Canada" gives the following formula used by Huchard in asthma:

Iodide of potassium,	
Tincture of lobelia,	
Tincture of polygala, each.....	10.00 grammes;
Extract of opium.....	0.10 gramme;
Distilled water.....	250.00 grammes.

Dose, a teaspoonful morning and evening.

An Ointment for Hæmorrhoids.—The "Revue de thérap." gives this formula for an ointment to be used for hæmorrhoids,

Camphorated ointment.....	32.00 grammes;
Powdered galls,	
Acetate of lead, each.....	10.00 grammes;
Extract of belladonna.....	0.25 gramme.

Apply from two to four times daily.

Cholagogue Pills.—The "Union médicale" publishes the following formula, suggested by M. Guéneau de Mussy:

Resin of podophyllum.....	0.025 gramme;
Euonymin.....	0.05-0.10 gramme;
Extract of hyoscyamus.....	0.05 gramme.

This is made into one pill. Extract of belladonna, 0.01, may be substituted for the hyoscyamus.

M. Blondeau (in the same journal) suggests, instead of this pill, the following:

Extract of hyoscyamus.....	0.01;
Extract of nux vomica.....	0.01;
Resin of podophyllum.....	0.005;
Soap.....	0.05.

From one to three such pills are to be taken at bedtime.

Both of these prescriptions are recommended for the vomiting of pregnancy also.

Lectures and Addresses.

REMARKS ON
MEDICINAL AND NON-MEDICINAL
THERAPEUTICS.

AN ADDRESS DELIVERED AT THE FIRST ANNUAL MEETING
OF THE NEW YORK STATE MEDICAL ASSOCIATION,
TOWN, NOVEMBER 20, 1884.

By AUSTIN FLINT, M. D., LL. D.

IN order that the scope of my remarks may be apprehended at the outset, it is necessary to define the terms embraced in the title of this address.

The term therapeutics may denote only the employment of medicines, that is, drugs. This is a limited sense of the term. In a broader sense it comprehends the treatment of diseases not by medicines alone, but any means or appliances. The latter is the more correct definition according to the etymology of the term (*θεραπεύω*), and in this sense I shall now use it.

The term medicinal, as I shall use it, is restricted to the employment of drugs.

The title which I have chosen might be otherwise expressed as remarks on the treatment of diseases with and without drugs.

From time immemorial it has been considered to be the chief office of the physician to prescribe and regulate the employment of drugs. Not entering at all into the past history of medicine, let me ask, What is the prevailing popular sentiment at the present time, in all countries, respecting the part which medicinal therapeutics play in medical practice? Is it not that the practice of medicine exclusive of the use of drugs would be like the play of "Hamlet" with the part of Hamlet omitted? How many patients at this day would be satisfied to be treated for an illness without drugs?

Several years ago my friend, Professor Alfred Stillé, visited with me my wards at Bellevue Hospital. I pointed out a patient who had recovered from pneumonia, the disease having passed through its course in the most favorable manner. As we were leaving the patient he exclaimed, in a tone of much irritation, "No thanks for my getting well; I have not had a particle of medicine since I came into the hospital." The case had been left to nature, and nature had effected the recovery as quickly and as completely as possible; yet the patient was much aggrieved, and felt that he had been neglected. Now, had he been treated with perturbatory medicinal agents, which might have induced ailments in addition to those incident to the disease, perhaps prolonging the duration of his illness and rendering his convalescence tedious, doubtless he would have been satisfied, and possibly have felt grateful to his physician. Have not many of those whom I now address met with analogous instances in which patients, having been subjected to little or no medication, have manifested after recovery no sense of obligation for medical services? Some may even have reproached themselves for having incurred the unnecessary

expense of medical attendance, and may perhaps have declined to make an adequate pecuniary compensation. Professional visits not supplemented by requisitions on the apothecary are deemed by many valueless. The worth of medical attendance is measured, in the minds of not a few, by the number of drugs prescribed. How generally, after a consultation, is it asked, "What new remedies are to be given?" and how often a feeling of disappointment, if the consulting physician has simply concurred in the propriety of the remedies already in use, leads to the reflection that a consultation might just as well not have taken place!

The twofold sense of the term medicine is significant. In one sense of the term medicine denotes "a science, the object of which is the cure of diseases and the promotion of health." In another and the more popular sense the term denotes a medicinal agent or a drug. The same is true of the term physic. Up to a late period this term was used in a sense synonymous with the term medicine as the name of a science. Popularly the term physic means a drug, and especially a purgative drug. These facts are cited to show that outside of the medical profession the practice of medicine and medicinal therapeutics are regarded as about one and the same thing.

It is a general impression with those who are not of the medical profession that eminence in this profession is based chiefly on superior attainments in medicinal therapeutics. The fact that one may be an accomplished anatomist, an erudite physiologist, a profound pathologist, and a distinguished diagnostician, irrespective of extraordinary knowledge or skill in the medicinal treatment of diseases, is not appreciated. In this point of view, the science of medicine in the popular mind is identified with the employment of drugs.

Now, it is needless to argue before this audience that a physician is not to be regarded purely as a prescriber of drugs; that the terms medicine and physic may have a broader and higher sense than that which limits their application to the *materia medica*, and that true eminence in the profession is by no means derived exclusively from medicinal therapeutics. I need not say that to withhold drugs in the treatment of cases of disease is as important an exercise of professional judgment as to employ them. In view of the prevailing popular errors just referred to, it is often more politic for the medical practitioner to employ than to withhold drugs. By withholding drugs he may not only disappoint the expectations of his patients or their friends, but he incurs a risk of having his disuse of drugs attributed to want of either knowledge of the disease or of interest in the case, and thereby to a withdrawal of confidence. The prevalence of these errors thus places the practitioner in a false position. Nothing is easier than to prescribe drugs. On the other hand, to refrain from their use may require, in addition to knowledge and judgment, not a little firmness and independence. An ignorant or weak practitioner, therefore, may be tempted to pursue a medicinal treatment in opposition to his judgment, or in order to cover up his lack of knowledge. Herein the popular errors may interfere with the usefulness of medical practice. Moreover, these errors

do injustice to the science of medicine as well as to the medical profession.

The time will come when the physician will not be regarded as solely a therapist, but as a medical counselor, whose functions embrace the preservation of health and the prevention, not less than the treatment, of diseases. Patients will then congratulate themselves, and be congratulated by their friends, whenever it is decided by the physician that potential drugs are not called for; but, as it should be added, drugs will then never be withheld if, in the judgment of the physician, they are indicated. This reformation, if I may so call it, is to be brought about by a change in popular ideas respecting the practice of medicine. Let the public understand that drugs are not to be employed, as a matter of course, whenever a physician is consulted or is in attendance. Let placebos be seldom, if ever, required for a moral effect. Let it be understood that, as modern clinical studies have demonstrated, many diseases end in recovery from an intrinsic tendency and self-limitation. Let it be popularly known that most medicinal agents are curative, not directly but indirectly, by the removal of obstacles in the way of recovery; that nature is always the efficient curative agent, and, therefore, that the physician is nature's servant, not her master. Let the value of medical science in the palliation of suffering and the promotion of the toleration of diseases which do not admit of recovery be fairly appreciated. When these desirable objects are accomplished, the medical profession will hold a position in public estimation higher even than it now holds; a more elevated standard of medical education will become a necessity, and the usefulness of the profession will be increased. Moreover, this reformation will prove the most efficient of the means for the protection of the public against irregular and illegitimate systems of medical practice, and, as may be added, against the unworthiness of those who profess to be regular or legitimate practitioners. The most popular of the systems opposed to legitimate medicine and the regular profession at the present time is based on the assumption that diseases are controlled by drugs, according little or nothing to a natural tendency to recovery. Correct popular ideas of medicinal and non-medicinal therapeutics are incompatible with confidence in this or any system of practice which assumes that recovery from diseases is always due wholly to medicinal agencies. Let correct ideas prevail, and there will be fewer instances than now within the ranks of the profession of unworthy means to secure a local reputation and to enhance the sense of obligation for professional services; in other and plainer language, there will be less of quackery within, as well as without, the medical profession.

As preliminary to the reformation in popular ideas to which I have alluded, there must be more unanimity than now exists in the medical profession respecting medicinal therapeutics. There is considerable diversity among physicians with respect to their estimation of the importance of drugs, and a corresponding diversity in practice. There are practitioners who, in this point of view, exemplify opposite extremes. Some practitioners have an excessive and unwarrantable faith in drugs; others are excessively and unwar-

rantly skeptical. Any practitioner who has a considerable number of acquaintances among his fellow-practitioners will readily recognize examples of each of these extremes. Pharmacomania is a form of mental aberration affecting alike certain physicians and patients. The latter have a morbid craving for, and the former an abnormal propensity to prescribe, drugs. If it so happen that a pharmacomaniac patient is under the care of a practitioner to whom that name applies, there may be mutual satisfaction, but, if not so mated, there is apt to be dissatisfaction on both sides.

The pharmacomaniacal practitioner never tires in the use of remedies. He has a distinct drug for every symptom, and remedies are multiplied in proportion as new symptoms appear. One may know that to this extreme a practitioner belongs by a glance at the array of phials, cups, and glasses at the bedside of the patient. The prescriptions, which accumulate daily, contain a multiplicity of ingredients, each, perhaps, designed for a particular object; or, to borrow a well-known comparison, they are like a heavily loaded shotgun—intended to do execution, although discharged without much regard to aim. His patients after recovery have a large collection of souvenirs consisting of the daily surplus of prescribed remedies. To the apothecary he is a "joy for ever." A catalogue of the medicaments presented by the apothecary as a memento shows that Molière did not exaggerate in the enumeration with which he opens his play "*Le malade imaginaire*." The pharmacomaniacal practitioner is never discouraged in the use of new remedies. He reads medical treatises and journals with special reference to these, and he loses no time in giving his patients the benefit of all in succession. As one new remedy after another becomes obsolete in consequence of having been found useless or injurious, he relinquishes it only to supply its place by one still more recent, always accepting the latest with as much avidity as he had accepted the remedies which he has discarded.

The practitioners who exemplify the opposite extreme, the skeptic, or, as may be said, the disbeliever, need not be delineated, inasmuch as the picture would be precisely the reverse of that just presented.

Truth, of course, lies somewhere between these extremes, and between the truth and the extremes are different gradations. Here, as in other instances, "*in medio tutissimus ibis*" is the conservative maxim. The practitioner who holds a just medium between the two extremes has sufficient confidence in medicinal agents, but, recognizing that in proportion to their potency they do either good or harm, he must be satisfied that they are clearly indicated before he employs them. He will not prescribe potential drugs at a venture, but only for a clearly defined purpose. He shoots after having taken deliberate aim, and he shoots with the rifle in preference to the shotgun. He requires competent testimony, based on trustworthy experience, before subjecting patients to the trial of new remedies. Fully alive to the progress of knowledge in medicinal therapeutics, he holds fast to what is actually known, and adopts what is new on satisfactory evidence afforded by his own experience added to that of others. He may make original observations with a view to enlarge the boundaries of our therapeutical knowledge, but

his observations are made with due precautions, not overlooking his responsibility for the welfare of his patients. His observations have for their sole object the discovery of truth for a beneficent end. He is conservative, but his conservatism is not foggyism. He cultivates and practices medicine as a science, but he never forgets that medicine is a science of which the pervading principle is humanity.

A fact not to be lost sight of is, that the only reliable basis of therapeutical knowledge is clinical experience. It is not sufficient to conjecture from the properties of drugs as to what they ought, reasoning *a priori*, to effect. It may take a long time for clinical experience to overthrow fallacious conclusions reached by such a method of reasoning. The results of experiments on lower animals must be accepted with caution. It is true that clinical experience is beset with difficulties which exemplify the Hippocratic axiom *experientia fallax*. The *post hoc ergo propter hoc* errors are often enough alluded to; nevertheless, they abound in the practice of medicine. How often can we be assured, when notable improvement has followed a measure of treatment, that the same improvement would not have followed the employment of a different measure, or if nothing had been done therapeutically! Great as are the difficulties in the way of determining the precise therapeutical value of drugs, clinical experience is the only tribunal from which there is no appeal.

It is a striking fact that our knowledge of medicinal agents, which are acknowledged to have the most special therapeutical value, until lately rested wholly on an empirical basis—that is, their *modus operandi* was entirely unknown. This is true of cinchona and other antiperiodic drugs, mercury and iodine in syphilis, and chalybeates prior to our present knowledge of anæmia. At the present time it can be said that the therapeutical value of cinchona, mercury, and iodine probably depends on their efficacy as parasitocides. This explanation came long after the discovery of the therapeutical value of these drugs. It is not easy to name drugs of equal therapeutical value, to the knowledge of which *a priori* reasoning led the way. Yet, although clinical experience is the only basis of our actual knowledge, analogical and speculative reasoning may, with propriety, precede the appeal to that tribunal. The explanation of the *modus operandi* of the remedies just named, together with the recent most important developments in ætiology, has given a direction to therapeutical observations which may lead to an immense advancement of our knowledge of medicinal therapeutics. I refer to discoveries respecting the parasitic origin of certain infectious diseases. Let the doctrine be established, as may be expected, that all infectious diseases are parasitical, and let the class of infectious diseases be enlarged, as may also be expected, and the therapeutical problem will be to ascertain by clinical experience a parasiticide for each parasite. Let this be accomplished, and therapeutics will have undergone a revolution the extent of which it is impossible to foresee. It is most inspiring to think of the luster to be conferred on medicine, and of the boon to humanity, by the ability to control all the essential fevers, together with septicæmia, epidemic cholera, influenza, pertussis, dysentery, and last, but first in relative

rank as a life-destroyer, pulmonary phthisis! Never before could the medicine of the future have appeared more bright and encouraging than at the present outlook.

My remarks thus far have had reference to medicinal therapeutics. In the same desultory way I shall offer some remarks on non-medicinal therapeutics.

As a rule, medical practitioners who overestimate medicinal therapeutics underestimate, in an equal ratio, non-medicinal therapeutics. The pharmacomaniacal practitioner is not likely to give much heed to non-medicinal measures of treatment. So, also, the pharmacomaniacal patient is prone to disparage and neglect measures which are non-medicinal. He places his reliance solely on the *materia medica*. It is perhaps true that drugs, oftener than non-medicinal measures, are used to an injudicious extreme, and that generally the evils of the former are greater than those of the latter; nevertheless, errors in the treatment of diseases irrespective of drugs are by no means infrequent, and may be productive of not a little harm. To some of these I shall advert. My remarks will relate to diet, to the use of alcohol, to "cold-catching," and to mental influences exerted upon patients.

Alimentation is not less an essential factor in therapeutics, as applied to both acute and chronic diseases, than in the maintenance of health. Certain fundamental principles of dietetic therapeutics are to be kept in view. One of these is that there is never danger from over-nutrition in either acute or chronic diseases. Whatever risk there may be of harm from an over-ingestion of food relates to the processes preliminary to assimilation and nutrition.

Another fundamental principle is that the immediate lethal agency, when diseases destroy life by slow asthenia or exhaustion, is chiefly innutrition. Graves acknowledged indebtedness for the suggestion of his plan of "feeding fevers" to a country doctor, who said that he seldom lost patients with fever provided they were not allowed to die of starvation. Now, what is true of fevers as regards the importance of a sustaining diet is equally true of all diseases which kill by slow asthenia. Death is due to starvation, and may be averted if effective assimilation and nutrition be practicable. In all chronic diseases which admit of recovery, this termination is the more assured and expeditious, as a general statement, the better nutrition is maintained. The tolerance of those diseases which do not admit of recovery and the prolongation of life are promoted in proportion as alimentation can be made conducive to nutrition.

It follows from these principles that, in cases of either an acute or a chronic disease, the question is not whether the patient is in danger of being over-nourished, but, on the contrary, whether alimentation is adequate to the capabilities of the processes relating to nutrition. Patients can not be over-fed so long as the food taken is digested, assimilated, and appropriated by the tissues. As it is impossible always to graduate with exactness the quantity of food to the digestive, assimilative, and nutritive powers, it is evident that the quantity must often either exceed or fall below the capabilities of the processes relating to nutrition. Now, of

the two evils, which is the lesser? I answer, an overplus of aliment, inasmuch as nature provides for a redundancy more than for a deficiency of alimentary supplies.

It is a sound maxim in medicine that the therapeutic indications derived from science and from nature, as a rule, should harmonize. If they be in conflict, the scientific indications are open to suspicion. I will add, as another maxim, that the true principles of therapeutics are, in accordance with the dictates of common sense. If there be antagonism here, when are considered the liabilities to error in scientific deductions, it is reasonable to suspect the correctness of the latter. These maxims are applicable to the dietetic treatment in diseases. Nature's indications as regards diet relate to appetite and the sense of taste. That appetite and taste were intended to govern the choice and quantity of aliment in health no one can doubt, especially if it be added that the indications derived therefrom are to be regulated, to a certain extent, by reason and experience. But it is a popular error that these natural indications are necessarily morbid in cases of disease, and that, instead of being recognized as constituting a governing principle, they are to be opposed. This popular error prevails to a certain extent in the medical profession. How often, perhaps I should say how common, is it that patients with different diseases are denied food when nature indicates the need of it by the sense of hunger! How common, when food is allowed, for patients to be denied the articles of food which they desire and made to take articles which they dislike! I look upon this disregard of nature's indications in the same light as upon the exclusion of fresh air from the sick-room, against which Sydenham was the first to rebel, and upon those restrictions in the use of water internally and externally which have not even now become obsolete. The dietetic regulations, in cases of disease, need reform to-day fully as much as reform was heretofore needed in regard to air and water. It is evidence that science is astray whenever it opposes, instead of co-operating with, the indications of nature.

There are, however, conditions of disease in which the instincts fail to express the needs of the system by means of appetite and taste, for the reason that the needs are not felt owing to morbidly blunted perceptions. These conditions exist in the essential fevers, especially typhus and typhoid fever. Under these circumstances the knowledge and judgment of the practitioner must, as far as practicable, take the place of nature's indications. Science must assume the control, whereas, under other circumstances, it should merely regulate the dietetic treatment under the governing influence of the instincts. The problem, then, is to satisfy the needs of nutrition as fully as possible, irrespective of any guidance by the instincts of the patient. Both reason and experience show how precious, under these circumstances, are the foods in which are combined, by the hand of nature, in due proportion, all the elementary principles—namely, milk and eggs. For these there are no substitutes. Supplementary thereto are the various farinaceous foods, and the animal foods other than those just named.

With regard to meats, a common error, both popular and professional, and one productive of a vast deal of harm,

is to consider their nutritive value as fairly represented by either infusions or decoctions, or by the juices obtained by pressure. The valuation by most persons outside of the medical profession, and by many within it, of beef-tea or its analogues, the various solutions, most of the extracts and the expressed juice of meat, is a delusion and a snare which has led to the loss of many lives by starvation. The quantity of nutritive material in these preparations is insignificant or *nil*, and it is vastly important that they should be reckoned as of little or no value, except as conducive indirectly to nutrition by acting as stimulants for the secretion of the digestive fluids or as vehicles for the introduction of nutritive substances. Furthermore, it is to be considered that water and pressure not only fail to extract the alimentary principles from meat, but the excrementitious principles, or the products of destructive assimilation, are thereby extracted; hence, not very inaptly, beef-tea has been compared to urine, and, a few years ago, a German experimenter, whose name I can not recall, declared that he produced fatal toxæmia in dogs by feeding them with this popular article of diet.

Meat liquefied and retaining all its alimentary principles is a great desideratum in dietetic therapeutics. The preparation known as Leube's Meat Solution consists of flesh brought by artificial digestion to the condition of peptones. It is an equivalent of the solid flesh, and, therefore, represents all the alimentary principles of meat. A late improvement in the preparation by Rosenthal has made it acceptable to the palate. This method of preparing meat in a liquid form should supersede most of the various preparations which are more or less in vogue. It is desirable that the merits of preparations after the methods of Leube and Rosenthal, not only of beef, but of the various kinds of meat, should be properly appreciated by physicians and patients.

Chewing meat and rejecting by expuition its nutritive constituents is a practice not less irrational, unscientific, and opposed by common sense, than disgusting. As a rule, if meat is craved and agreeable to the palate, it is allowable; and it is a shame to tantalize nature's cravings with the shadow, withholding the substance.

In leaving the subject of diet, I will express the belief that not a few maladies, more especially those affecting the nervous system, often originate in, and are protracted by, insufficient alimentation. Evidence of the correctness of this belief is afforded by the successful treatment of certain nervous affections in women after the plan inaugurated by Weir Mitchell, in which alimentation is an essential factor. In place of the senseless apothegm, "death in the pot," it might be more pertinently said, life in the pot, inasmuch as this utensil, if regarded as the symbol of aliment, represents health and vigor.

The question whether alcohol is a food has, within late years, given rise to much discussion and investigation. As I suppose, few, if any, now hold to the opinion that the sum total of alcohol ingested is eliminated from the body as alcohol, or deny that it supplies a material for the production of animal heat. It is, therefore, a food. All will

admit that it may be made a potential agent for either good or harm. The use of alcohol as a therapeutic agent should have no connection with its use or abuse in health, except as regards proper precautions lest its use in illness may eventuate in an alcoholic habit after recovery. A physician may be a zealous advocate of total abstinence in health, but evidently his zeal should not lead him to withhold alcohol from his patients whenever benefit is to be derived from its employment as a therapeutic agent. It were, indeed, a cruel injustice to patients to deny them this benefit because a vast amount of misery and crime is attributable to alcoholic intemperance. The value of alcohol in therapeutics and the indications for it are to be determined precisely as in the instance of any other therapeutic agent. Opium, like alcohol, is capable of abuse in health, but who will say that thereby it is any the less worthy of the eulogium of Sydenham, who called it the *magnum donum Dei*!

In the medical practice of the last century there have been notable oscillations in the use of alcohol as well as of other therapeutic agents. The doctrine of Brown, which, on purely theoretical grounds, led to its free use, was followed by that of Broussais, which stigmatized its use as incendiary on grounds equally theoretical. Its free use came again into vogue about forty years ago. Todd was then its ardent advocate, and he was, perhaps, the first to emphasize its agency as a food. Its use for several years was doubtless too indiscriminate, and carried to an extreme. At the present time there is considerable diversity of opinion and practice as regards its use among medical practitioners, but the tendency of late years has been to use it with more and more reserve. Where lies the truth between the extremes as regards the proper place of this agent in therapeutics? I shall not undertake to answer this question. It covers too much space to be considered on this occasion. I will only remark that the oscillations in the past and the diversity in practice at the present time show conclusively the need of further investigation. Here is one of the many questions in therapeutics which call for the analytical study of carefully recorded clinical experience.

I have endeavored to do something in the way of this study with reference to phthisis and the continued fevers.* As a conclusion based on the analysis of a considerable number of recorded cases, I feel warranted in affirming that, in a certain proportion of the cases of phthisis, alcohol antagonizes the progress of that disease, and that in the treatment of the continued fevers (typhus and typhoid) it is a means of saving lives which without it would be lost. Reasoning by analogy, it is a logical conclusion that with similar indications it is an important therapeutic agent in the treatment of essential fevers other than those just mentioned, and also of diseases of which fever is symptomatic.

It is a theoretical error, which I suppose to be common,

to regard the action of alcohol within the body as purely that of a stimulant. A cardiac stimulant it undoubtedly is, and this is one of the modes in which it is useful. But the prevention of the waste of tissues by acting as a substitute for their components in the production of animal heat is another rational *modus operandi*. And another, hitherto not so much considered as it probably will be under the guidance of pathological developments now in active progress, is its antiseptic property.

If alcohol is useful as a material for combustion within the body, it is indicated in the condition of fever prior to the indications for its employment to sustain the failing powers of life. The object, in this point of view, is to forestall these indications and prevent the asthenia giving rise to them.

It is yet to be ascertained in what diseases, and to what extent, alcohol may act as an antiseptic, or a parasiticide, or an antidote. It has been supposed to counteract the noxious effects of certain venoms. A similar claim has been made for it, on the basis of experience, in the treatment of diphtheria. The conjecture is not unreasonable that in other fevers it may have a controlling influence by destroying, either directly or indirectly, the special causative agent, whether this be, or be not, a morbid organism. Here is an object for clinical observations. It is evident that, employed with a view to test fairly its value as an antiseptic, or a parasiticide, or an antidote, in different diseases, it may be important that alcohol be employed early, continuously, and in a quantity as large as may be tolerated. In its employment for these purposes, as also for the support of the vital powers, the greatly increased tolerance of alcohol in different diseases, and in different cases of the same disease, must be taken into account.

The phrase to "catch cold," so often in the mouths of physicians and patients, is a curious solecism. It implies not only that the term cold denotes something positive, but that this something is a living entity, a sort of demon in ætiology, which does not catch, but is caught by, the unfortunate victims. The synonym *Erkältung* pervades German medical literature remarkably. There are few diseases in the nosology in the causation of which "catching cold" does not enter, according to German writers. At the present time a question under discussion in Germany is whether pneumonic fever is attributable to "catching cold," and there appears to be an emancipation of the minds of some of the most distinguished of the physicians of that country from the traditional notion that this disease is the work of the ætiological evil spirit represented by the term "cold."

There is an indefinite latitude in the phrase to "catch a cold." The phrase is used to denote an inflammation or a catarrh of the mucous membrane of the air-passages, but its application is extended to various affections in various situations. There is but little ground for its application to the ætiology of the so-called nasal, pharyngeal, laryngeal, and bronchial catarrh; but I shall confine my remarks to the supposed danger of "catching cold" as involved in therapeutics.

* *With the following:* "Clinical Report on Pulmonary Tuberculosis; giving an Account of Twenty-four Cases of Arrested Tuberculosis, etc.," "Am. Jour. of the Med. Sciences," January, 1858.—"On the Management of Pulmonary Tuberculosis, with special reference to the Employment of Alcoholic Stimulants," "Trans. of the N. Y. Acad. of Med.," 1863.—Treatise on "Phthisis: its Morbid Anatomy, Ætiology, etc.," pp. 446, 1875.—"Clinical Reports on Continued Fevers, based on an Analysis of 164 Cases," pp. 390. Buffalo, 1852.

If most persons outside of the medical profession were to be asked what they considered as chiefly to be avoided in the management of sick people, the answer would probably be "catching cold." I suspect that this question would be answered in the same way by not a few physicians. Hence it is that sick-rooms are poorly ventilated, and patients are oppressed by a superabundance of garments and bed-clothes. The air which patients are made to breathe, having been already breathed and rebreathed, is loaded with pulmonary exhalations. Cutaneous emanations are allowed to remain in contact with the body, as well as to pervade the atmosphere. Free exposure of the body is deemed hazardous, and still more so bathing or sponging, the entire surface of the body being exposed. Patients not confined to the bed, especially those affected with pulmonary disease, are overloaded with clothing which becomes saturated with perspiration, and is seldom changed for fear of the dreaded "cold."

These sketches are from life, and the observations of every medical practitioner furnish real illustrations. The supposed morbid agency of cold is a traditional error deeply rooted in the popular mind. It interferes often, in no small degree, with the satisfactory management of cases of disease. It is an obstacle in the way of securing for patients hygienic conditions, the importance of which may be greater than that of drugs. It is obstructive to the adoption, in cases of fever, of the antipyretic treatment, which is, perhaps, the most important of the improvements in modern therapeutics. How reluctant are physicians, on account of traditional ideas, to make trial of either the cold affusion of Currie, the cold bath, the wet sheet, or even sponging of the body, in cases of pneumonic fever, although testimony is ample of the safety and utility of these measures of treatment! Of those who are convinced of the safety and utility of these measures, how many hesitate to resort to them lest, if the termination be fatal, the death might be attributed to a therapeutic innovation so opposed to popular prejudice!

A reform is greatly needed in respect to "catching cold." Let the demon be exorcised first from the medical, and next from the popular, mind! Let it be generally known and believed that few diseases are referable to the agency of cold, and that even the affection commonly called "a cold" is generally caused by other agencies; or, perhaps, by a special agent which may prove to be a microbe. Let the axiom, "a fever patient never catches cold," be reiterated until it becomes a household phrase! Let the restorative influence of cool, fresh, pure atmosphere be inculcated! Let it be understood that in therapeutics, as in hygiene, the single word *comfort* embodies the principles which should regulate coverings and clothing. Non-medical therapeutics will have gained much when this reform is accomplished.

My concluding remarks will have reference to mental influences to be exerted on patients.

I have often thought that a consideration of the influences which the physician may exert, either for good or harm, on the minds of his patients, should hold an important place in therapeutics. Our text-books are silent on this subject, and

I am not aware that much, if any, attention is given to it in oral teaching. It can not, however, be doubted that success in the management of cases of disease often depends largely on mental influences conjoined with other measures of treatment.

The mental constitution of some practitioners is unfortunate as regards the exertion of favorable influences on the minds of patients. As we all know, there are members of our profession with no lack of ability or of educational requirements, who are irreproachable in character, whose manners are unobjectionable, and who are in all respects gentlemen, but who are not successful in medical practice. Something is lacking which it is not always easy to define. There is a loose screw in the mental mechanism, the effect being an inability to inspire patients with confidence, faith, and hope—three potential elements in therapeutics. It is fortunate for the physician and for patients if this lack of constitutional fitness for the practice of medicine is discovered early, and if it lead to the adoption of some pursuit to which there is a better adaptation.

There are certain rules bearing on the influences to be exerted on the minds of patients which should be considered and adopted, although they may not accord with the natural temperament or disposition of the practitioner. Here, as in other instances, we find in the practice of different physicians two extremes which are widely apart. Here, too, is applicable the trite maxim, "*In medio tutissimus ibis.*" Let me endeavor to sketch an illustration of each extreme.

I have in my mind's eye the picture of a practitioner whose mental temperament is in a high degree sanguine and hopeful. It is difficult for him to look in any other direction than the bright side of a case. His attention fastens on all the encouraging points. He instinctively exaggerates these, and undervalues those which are discouraging. All the possibilities as regards a favorable progress and termination he believes will be made available for his patients. He is confident that his cases will prove, if need be, exceptions to general rules.

This is a rough outline of one extreme—an extreme of optimism. Practitioners who exemplify this extreme are liable to errors of prognosis. They lose patients when they had entertained and held out confident expectations of recovery. For this they may incur blame. But there is reason to believe that these expectations not infrequently contribute to recovery, and, as regards an influence on the issue of disease, they assuredly do not do harm to the patient.

A picture illustrative of the opposite extreme represents a practitioner who assumes the responsibility of a case always anticipating the worst that can befall the patient. His solemn manner and melancholy mien inspire nothing but forebodings. His attention is intent on the discovery of bad prognostics. He shakes his head distrustfully at symptoms which appear to be favorable. His words of encouragement, if he venture upon them, are so qualified by his apprehensions as to give rise to fear rather than to hope. This is an outline of a medical pessimist. The errors of prognosis into which practitioners of this stamp fall are the opposite of those of the optimist. Patients recover who

have been condemned to die. These errors are less likely to occasion blame than those which involve fallacious expectations of recovery. But, it is to be added, a gloomy or fatal prognosis may contribute to its fulfillment.

It would require some presumption to draw a picture illustrative of a *juste milieu* between these extremes. The little space which remains on this occasion precludes the attempt were I disposed to make it. I will close with a few fundamental precepts pertaining to mental therapeutics, stated dogmatically and aphoristically, for the sake of brevity.

The practical object in mental therapeutics is to promote the favorable progress of diseases by means of influences exerted on the minds of patients.

The influences which may be exerted on the minds of patients are of sufficient importance to constitute a distinct branch of non-medicinal therapeutics.

Abnormal mental conditions, although the intellectual faculties may not be materially impaired, often lead to an exaggeration of symptoms, imaginary ailments, and undue apprehensions, which interfere with the favorable progress of diseases by affecting appetite and digestion, by preventing sleep, by discouraging co-operative efforts for restoration to health, and by a general depressing effect upon the functions of the body. The methods for the removal of these obstacles in the way of the favorable progress of diseases are within the province of mental therapeutics.

Confidence, hopefulness, and courage are conducive to the favorable progress of diseases. To endeavor to secure and maintain these is a duty incident to mental therapeutics.

Observation teaches that the strength of the mental faculties in health and the extent of attainments in any branches of knowledge are in no measure reliable criteria for judging of the mental condition of patients affected with disease. This assertion may be applied even to moral qualities and religious convictions. Disease is the great leveler intellectually and morally, as well as physically. Men and women often become on the sick-bed, in a mental and moral point of view, children, and are to be managed as such. Shakespeare, as always, was true to nature when he compared to a sick girl the imperial Cæsar when suffering from a paroxysm of intermittent fever.

In contrast to the assertion just made, every physician of much experience has met with instances exemplifying the efficacy of determination and a strong will in resisting and overcoming disease. To recognize and endeavor to fulfill nature's indications, as regards the potential influence for good which the mind can exert over the body, is a duty incident to mental therapeutics.

Instances are not infrequent of the efficacy of an intense belief in the curative power of certain measures under circumstances which, to the superficial observer, appear to prove conclusively a special intervention of Providence. The so-called faith cures, and those which follow the laying on of hands, or other procedures in themselves inoperative, except through the mind, are full of significance as regards the potential agency of measures pertaining to mental therapeutics. The history of Perkinism and the prevalence, now and heretofore, of other medical delusions are most instruc-

tive, and have, perhaps, not been sufficiently considered with respect to the lessons to be drawn therefrom, and their practical applications to legitimate medicine.

The influence of mental activity, under an absorbing sense of duty, on the tolerance of diseases might be illustrated by many examples. Kane endured the hardships of an expedition toward the North Pole with a diseased heart. General Gordon, who at this time holds a prominent place in the thoughts of all Christendom, is a sufferer from angina pectoris. To quote his own words, "I may say that I have died suddenly over a hundred times." The London "Lancet," referring to the subject, expresses the hope that he (General Gordon) may "long continue to show to the world what can be done by men with grave diseases, but with faith in their own mission and in God's providence." It is this faith which is a potential factor in the tolerance of disease. The other side of this picture shows that pitiful introspection exemplified in so many of our patients and which is as potential for harm as the worthy aims which absorb the mental faculties are effective for good.

I do not doubt that many a life has been shortened by injudicious injunctions to rest from labors which, from their nature and long continuance, had become indispensable to health as well as happiness. The sanitary agency of work is too often overlooked. How wretched often is the remainder of life when, either for the delusive expectation of happiness or the equally delusive expectation of improved health and length of days, activity is exchanged for idleness. Insanity and suicide are not infrequent consequences. The introduction into medical nomenclature of the term nervous asthenia, for which I am responsible, and that of the congeneric terms neurasthenia and nervous prostration, subsequently introduced, I am bound to say, have done harm, although they express veritable pathological conditions. These terms have done harm by expressing a condition which is often imaginary, and by leading to the evils resulting from physical and mental inactivity.*

The physician who appreciates the importance of mental therapeutics, and of the duties incident thereto, will not fail to hold out to patients the encouraging features of a case. He will not give way to gratuitous forebodings. He will be circumspect in forming, and still more in announcing to his patients, an unfavorable prognosis. He will be slow to hazard a prediction as to the precise date that a disease will prove fatal, and still less will be guilty of the brutality of imitating a judicial sentence of death. He will keep out of the view of his patients discouraging possibilities, but not those which warrant hope. He will strive judiciously and skillfully to bring to bear all the potential mental agencies of which he may properly avail himself. He will throw on the scale of hopefulness all the weight to be derived from those doubts and difficulties which beset diagnosis and prognosis. He will make due allowances for the limitations of medical knowledge and his own deficiencies.

* The term "nervous asthenia" was introduced by me in the first edition of my treatise on the "Principles and Practice of Medicine," published in 1866. Afterward the term neurasthenia was introduced by the late Dr. Beard. Nervous prostration is a popular term much used at the present time.

I have alluded to some of the precepts which underlie mental therapeutics. A consideration of the various modes of exerting influences on the minds of patients would embrace manifold details. Many questions arise in regard to the course to be pursued under the varied circumstances incident to disease and to the diversities of human character. Some of these questions involve points in casuistry. The subject in its practical aspect has a wide scope, and I commend it to some one who may aspire to be the author of a work on the non-medical treatment of diseases, according a proper relative space to the influences to be exerted on the minds of patients, or, in other words, to mental therapeutics. Such a work is a desideratum in medical literature.

Original Communications.

A CASE OF

IMPACTED EXTRA-CAPSULAR FRACTURE OF THE NECK OF THE THIGH BONE.*

By JOSEPH C. HUTCHISON, M.D.,

BROOKLYN, N. Y.

On the 31st of August, 1883, two gentlemen, one a medical man, fifty-six years old, weighing two hundred and four pounds and enjoying robust health, drove, in a high-top buggy, from Lake Luzerne to Lake George, in order to make a professional visit. The horse seemed to be perfectly gentle, and required a good deal of urging to make him accomplish the trip in a reasonable time. The "turn-out" was furnished by a livery stable.

They drove up to the piazza of the Fort George Hotel, stopped, and, as they were preparing to get out, the horse suddenly started to run, and, making a short turn, the wheels became locked, the buggy was upset, and the occupants were thrown violently to the ground.

A medical gentleman, who saw the accident, hastened to assist his professional brother to get out of the way of the horse, which, after running some distance, turned and came back over the same road, with the fragments of the wagon dangling at his heels, apparently with the purpose of finishing his work of destruction.

The doctor had walked, with a little assistance, five or six steps, to get out of the way of the running horse.

He suffered deep-seated and severe pain in the right trochanter major, which received the force of the blow, and at once concluded that he had an impacted extra-capsular fracture of the thigh bone. This opinion was based upon the fact that the pain in the trochanteric region was excessive, and it seemed impossible that so heavy a man, thrown violently to the ground from such a height and striking upon the trochanter, could have escaped this fracture; and he inferred that the fragments were impacted, because he had been able to take a few steps after the injury. So sure was he of his diagnosis that he requested the surgeon, who was on the spot and assisted him in getting out of the way of the horse, not to manipulate the limb for fear of disturbing the impaction. He did not lose consciousness, nor did he suffer from shock in the slightest degree.

The other gentleman got up immediately without assistance,

but was greatly shocked, and it was subsequently found that he had a broken rib.

Soon after the doctor was put to bed he was carefully examined by Dr. W. H. Hall and Dr. G. E. Munroe, who were summing at the hotel, and also by Professor Frank H. Hamilton, who was staying at a neighboring hotel. Two of the surgeons found from one half to two thirds of an inch shortening of the limb; the other, after repeated examinations, satisfied himself that there was no shortening.

There was no version of the limb, and the patient was able to invert the foot to a moderate degree; there was considerable pain in the right groin, and also in the trochanter. The pain in the trochanter was relieved instead of being increased by pressure. The skin was contused directly over the outer side of the trochanter, showing that the fracturing force was applied transversely to the axis of the neck of the femur. The absence of bruises at any other part of the surface proved that the trochanter had received the full force of the fall. No manipulation was made for the purpose of detecting crepitus and settling definitely the question of fracture. A positive diagnosis was not expressed at this time by the attending surgeons.

During the night the patient suffered greatly with pain about the upper part of the femur, which was aggravated by muscular spasms whenever he fell asleep. He was relieved in a great measure by lying upon the right trochanter, the pressure of the bed against it acting as a splint. He could not raise the heel from the bed, but was able to flex the thigh slightly upon the pelvis by bending the knee joint.

On the following morning Dr. Hamilton observed depression of the right trochanter, and an unnatural fullness in the inguinal region, which, with the development of muscular twitches during the night about the seat of injury, in addition to the signs previously mentioned, convinced him that there was an impacted extra-capsular fracture. Dr. Hamilton stated that he regarded muscular spasm in this region, after a recent injury, as generally pathognomonic of fracture of the cervix femoris—a statement which the writer does not remember to have seen mentioned by any author.

The patient was advised to get to his home, two hundred miles distant, as soon as possible. No apparatus was applied, because it would have increased the inconvenience of transportation, and the surgical knowledge of the patient would induce him to keep the limb quiet and in the best position to prevent separation of the fragments. Owing to the crowded state of the cars at that season of the year, great difficulty was experienced in securing proper transportation. Finally, by the unwearied exertions of a friend, a private car was obtained from a distant city, and the patient was conveyed to it from the hotel very comfortably on an improvised stretcher.

The transportation from the hotel to the city was under the direction, chiefly, of Dr. J. H. Sterling, of Brooklyn.

The stretcher was borne by six men, two others accompanying it as a relief. The patient turned himself upon his right side, so that the trochanter major was well pressed upon. The transportation to the car was comfortably made, and he was placed upon a spring mattress upon the floor. Soon after leaving Lake George, the car, which was the last on the train, bumped violently against the one in front, producing severe pain at the seat of fracture. A second bump took place with a like result, and then the superintendent had the car well manned with a hand-brake, which prevented any further concussion.

The patient slept moderately well during the remainder of the night, and reached the Forty-second Street depot at 7 A. M. the following morning, where he was met by an ambulance, which had been kindly furnished by the Brooklyn Health Department, and was conveyed to his residence. He was driven

* Read before the New York Surgical Society, November 11, 1884.

through New York and Brooklyn at a moderate pace, and expressed great satisfaction with his comfortable ambulance experience. He was strongly impressed with the superiority of this method of carrying the sick and injured over those formerly used. Before leaving the depot, a long splint was applied to the outer side of the injured limb, but the patient, finding it irksome, removed it and again turned over on his trochanter. On reaching home he was placed upon Hooper's invalids' bed, which he had purchased two years before in London, not with the expectation, however, that he would be the first to use it. He was then allowed to rest undisturbed until the afternoon, when Buck's dressing was applied by Dr. A. R. Paine, assisted by Dr. Rand. A ten-pound weight was used, not for extension, but to steady the limb and to relieve muscular spasm. This was soon reduced to seven pounds, with the addition of another pound at night. Lateral pressure was then made against the trochanter by means of a heavy bag of sand. This was suggested by the relief afforded the patient by lying on the trochanter before the leg was dressed. The pressure was kept up night and day for thirty-five days, and the patient was on the alert to have it closely applied, because it gave him great relief. During that night, and for three succeeding nights, the muscular twitches returned whenever he fell asleep, which gave him great pain at the seat of injury, lasting for half an hour. These spasms of pain were alleviated somewhat by fifteen drops of Magendie's solution of morphine at bedtime. On the third day after reaching home, five days after the accident, our patient requested Dr. W. S. Halsted to send him his modification of Volkmann's splint, which he intended to have applied if loosening of the fragments and eversion of the limb should take place. He believed that this apparatus would be more comfortable, if not more efficient, than the long external splint in controlling eversion. Dr. Halsted kindly brought the apparatus himself, and the patient and surgeon in charge acceded to his suggestion to apply it at once. As there was no separation or loosening of the fragments, and therefore no eversion of the foot, the only advantage that Halsted's splint had in this case over Buck's extension alone was that it enabled him to move more easily up and down in bed. Toward the end of the third week a marked, painless swelling, unmistakably callous, was noticed in the groin, just outside the femoral vessels, which disappeared in due time. On the fortieth day the dressings were removed; on the forty-second day the patient got out of bed and, by the aid of a chair, crossed the room to a lounge; on the following day he moved about on crutches, and on the eighty-fourth day he laid aside his cane. During the whole period of his confinement to bed all his functions were regularly and normally performed, and he felt perfectly well after the pain from the muscular twitches during the first week had subsided. Eleven months after the injury there is nothing to indicate that the patient has had a fracture of the thigh except the diminished prominence of the trochanter major, flattening of the corresponding side of the nates, and an unnatural fullness in the inguinal region; there is no limp, the motions of the joint are perfect, there are no osteophytes, and he exercises on horseback with as much pleasure and comfort as formerly.

It will be observed in the history of this case that two of the most important signs of fracture of the neck of the femur, whether impacted or not, were absent—viz.: pain on pressure over the trochanter, and eversion of the limb. Pressure against the trochanter major, instead of aggravating the pain, gave great relief, and, on that account, was constantly kept up; first, by lying upon the trochanter, and, after the apparatus was applied, by means of a large

sand-bag. There was absolutely no eversion, the position of the foot was normal, and the right foot can now be inverted and everted as far as the left.

Outward rotation of the limb, in impacted as well as other fractures of the cervix femoris, is the rule; but exceptional cases are recorded where the limb was inverted or the position of the foot was normal, turned neither in nor out. The position depends upon the direction of the fracturing force.

This fracture is produced, in a great majority of cases, by falling forward and on the side, striking the front and lateral aspects of the trochanter. The force applied in this direction would inevitably produce posterior impaction, and eversion as a consequence. But, if the force is received upon the outer and posterior aspect of the trochanter, the anterior wall will be impacted, and we shall have inversion of the limb. And when the fracturing force is applied directly upon the outer surface of the trochanter, in the direction of the axis of the neck, as in the case here reported, the whole base of the cervix is implanted into the trochanteric portion of the femur, and the limb will retain its natural position.

When we remember that inequality in the length of the lower extremities is often a normal condition (which may have existed in this case), that there was no pain on pressure over the trochanter, that the foot rested directly upon the heel, and that the recovery was so rapid and complete, the question may naturally arise, Was this a case of fracture, or was it an injury which did not involve the integrity of the bone? Every experienced surgeon is aware of the difficulties sometimes attending the diagnosis of fracture of the neck of the femur, especially when the upper fragment is firmly implanted into the cancellated tissue of the lower. A majority of the symptoms of fracture may be present in cases in which the neck of the femur is uninjured; and, on the other hand, fracture may be unaccompanied at first by the more important of the usual diagnostic signs. In cases of violent contusion of the periarticular muscles of the hip, all the component parts of the joint having received a severe shock—the result of a fall upon the trochanter—the symptoms are at first almost identical with fracture. In either case there may be eversion of the foot, shortening of the limb, which existed prior to the injury, an absence of crepitus, and an inability to raise the extended limb from the bed by a voluntary effort. In such a case, how are we enabled to ascertain the real nature of the injury?

This can generally be done by observing the relation which the trochanter major bears to the anterior-superior iliac spine. When the relative position is the same on each side, it usually indicates that there has been no other injury than contusion; but when it is altered, in a joint previously healthy, it denotes the presence of fracture.

A change in the normal relation of the two processes does not, however, always indicate the existence of fracture. A change in the position of the trochanter major, with reference to the iliac spine, may have been produced by chronic rheumatism of the hip joint. In such a case the bearings of the trochanter, with respect to the iliac spine, will not serve as a diagnostic mark between a contusion of the hip

and an impacted fracture of the neck of the femur. The previous history of the case will, however, assist in determining the nature of the lesion.

In investigating these injuries we should not form our opinions from any particular symptom, but all the symptoms which the case presents should be considered in order to arrive at a correct diagnosis.

In the case under consideration, the pathognomonic symptoms of fracture were:

1. Depression of the trochanter major on the injured side. This process was, according to the measurement of Dr. Halsted on the fifth day after the injury, three quarters of an inch nearer the iliac spine on the right than on the left side.

2. The spasms or twitchings in the muscles surrounding the joints during sleep, and continuing for five days.

3. The deposit of callus, toward the end of the third week, in the groin, on the outer side of the femoral vessels, and just below Poupert's ligament.

An interesting incident in the case was the variation in measurements by the three surgeons who first saw the patient—all men of large experience in the treatment of fractures. This is, I believe, not an uncommon experience. We can not always be sure that we have measured from exactly corresponding points on the anterior-superior spinous processes of the ilia.

Before getting out of bed, measurements were repeated by Dr. E. R. Squibb and Dr. A. R. Paine with great care. They found from a quarter to a third of an inch shortening. On June 14th the patient was measured by Professor Frank Hamilton, who found only one sixth of an inch shortening. He remarked that he had never before seen so good a result after such an injury.

The small amount of shortening indicated that the impaction was not deep, and yet it was enough, with intelligent care on the part of the patient, to prevent separation of the ends of the fragments. The diagnosis of fracture was sufficiently clear in this case without manipulation, but, had there been a reasonable doubt of the nature of the injury, violent manipulations would have been manifestly improper. The utmost caution was observed in examining the limb.

In any case of suspected impacted fracture of the cervix femoris the discreet surgeon will prefer to treat the case as one of fracture rather than incur the risk of damaging his patient by instituting such an examination as is necessary to produce crepitus. This rule should be observed even when the bone is not impacted in the best position. It is better that malposition of the limb should not be corrected than that impaction should be broken up by unwarrantable manipulation, and the union of the fragments thereby endangered. The most important feature in the treatment of such cases is, therefore, to maintain the impaction. This can be best accomplished by keeping the patient at rest, by avoiding undue manipulations, by moderate extension in the straight position to steady the limb, and by lateral pressure over the trochanter by means of a sand-bag, or a long external splint.

Violent extension would disengage and displace the im-

acted fragments, and make non-union almost inevitable. If, for any reason, it is necessary or desirable for the patient to get out before firm union of the fracture has taken place, this may be done with safety, at the end of the fifth week, by applying one of Johnson's felt splints, or some similar appliance, enveloping the body to midway between the hips and axilla, and the thigh and leg to midway between the knee and ankle. The felt is made pliable by holding it before a fire or immersing it in hot water, or, still better, by covering it with a wet cloth and softening it by a hot smoothing-iron. It is then applied over a tight-fitting pair of drawers and rapidly covered with a bandage. The splint adapts itself to all the inequalities of the surface, and, if well applied, does not make undue pressure at any point.

Our patient amused himself by applying this splint to the sound limb while in bed, and found that it made the joints absolutely immovable. The objection suggested to its use is the danger of disturbing the fragments during its application. It is much lighter than plaster-of-Paris bandages, can be applied with more facility, and with less danger of deranging the fragments. The rapid and perfect recovery were interesting features in this case, and were duly appreciated by the patient. He knew that a more perfect result would be obtained by establishing motion in the joint as speedily as practicable. He had never permitted a patient to get out of bed so soon, nor would he do so now, notwithstanding his own favorable experience, unless the patient were a cautious surgeon and fully appreciated all the circumstances of the case.

THE SURGICAL MANAGEMENT OF RHACHITIC DEFORMITIES OF THE LOWER EXTREMITIES.*

By V. P. GIBNEY, A. M., M. D.,

PROFESSOR OF ORTHOPEDIC SURGERY IN THE NEW YORK POLYCLINIC.

It is my impression that the subject of osteotomy for genu valgum and genu varum has not been discussed in any of the New York societies except the Surgical. Certainly the Academy of Medicine has not contributed anything to science bearing upon the question, and I therefore ask no pardon for presenting this evening a paper on "The Surgical Management of Rhachitic Deformities of the Lower Extremities."

If my paper shall serve to bring out a discussion among men whose experience is large and valuable; if some, as yet, mooted points can be settled within this hall, so far as the weight of statistics and opinion can settle any point; if aught can be added, however small, to our stock of information on the subject of bow-legs, of knock-knee, and of other curves of the lower extremities—I shall feel that I have not written in vain.

By way of definition, let me state that in the employment of the term surgical management I wish to convey the impression that mechanical appliances as well as cutting

* Read before the New York Academy of Medicine, November 20, 1884.

instruments are surgical means for effecting relief. He who devises and applies apparatus to meet indications may be just as much a surgeon as he who wields the scalpel, the osteotome, and the mallet. It requires as much skill, aye, more skill, to make a simple fracture always at the epiphyseal line than to make a compound fracture at this point.

If, then, I speak of braces and splints and osteoclasis, do not think that I am digressing. All these belong to the armamentarium of the surgeon.

For the reason that a large proportion of bone-curves and epiphyseal changes in the lower extremities are found in children who have been or are rachitic, and for the reason that the surgical treatment is the same whether the curve is rachitic or otherwise, I have advisedly made use of the foregoing terms in the selection of my title.

Despite the teachings of gentlemen who practice osteotomy, the great bulk of the profession, I am convinced, hold to the opinion that every case of knock-knee or of bow-legs does not demand surgical interference. Exaggerated cases are known to recover spontaneously, and there are practitioners who believe this and discountenance the use of splints or the resort to operation.

Accordingly, I have thought it desirable to raise the question—

What cases can be safely left to nature?

When I have asserted that many children do recover from deformity without any treatment whatever, I am met with the reply, "They did not have true cases of knock-knee or of bow-legs." The term knock-knee is the vulgar name for entogonyancon (esogonyancon). Macewen gives genu valgum, or genu introrsum.

Dunglison—our American authority on definitions—gives entogonyancon (I hope I shall not have to use this term again!) as meaning "bending of the knees inward."

Dr. William J. Little employs the term "in-knee," and has written an excellent brochure on "In-Knee Deviation." He means a "distortion of the knee joint," and hence his definition includes many deformities we are loath to speak of as knock-knee.

Dr. William Macewen defines by describing in the following language: "In the normal limb, a line drawn from the head of the femur to the middle of the ankle joint passes through the center of the knee joint; in knock-knee the middle of the knee joint is thrown to the inner side of this line."

Dr. Poore, the most recent author, gives as definition: "A deformity at the knee joint in which a line drawn from the head of the femur to the middle of the ankle joint passes outside the center of the knee joint, and in which the internal malleoli can not be made to touch when the limbs are in an extended position."

In the next paragraph he modifies this by stating that "not all cases of in-knee are cases of true genu valgum." By this he excludes "spastic contraction," some cases of disease of the knee joint, etc. His definition does not include as much as Dr. Little's does.

However, it is well understood by practitioners what is meant by knock-knee, and, as my remarks just now concern the cases that recover spontaneously, there is no occasion

for including deformities due to the diseases I have mentioned.

Do any cases of knock-knee—true knock-knee—recover spontaneously?

It is my opinion—indeed my opinion takes the form of a strong conviction—that a fair proportion of the cases of knock-knee in children in the United States make a spontaneous recovery. Let me give my reasons:

1. From 1871 to 1877, inclusive, I saw, at the Hospital for the Ruptured and Crippled, two hundred and fifty-five cases of genu valgum in children under fourteen years of age.

This period antedated the advent of osteotomy as a means of redressing these deformities. This represents a period, too, in which the apparatus employed for relief was theoretically inoperative.

Practically it seemed to be of service. The patients wore the springs from six to eighteen months, and in many, yes, in nearly all, the limbs were restored to a normal condition. The construction of the appliance is as follows: Steel bars of medium strength extending along the outer sides of the limbs from foot-plate to pelvic-band with joints at the ankle, knee, and hip, permitting the fullest range of flexion and extension. Like bars along the inside, reaching from the ankle joint to the upper third of the thigh, and joined to the outer springs by means of semicircular steel bands at the upper extremity and at the calf. A joint at the knee, at which point a small pad was attached, not pressing firmly against the inner condyle. Both these springs were attached at the ankle to a foot-piece which was worn within the shoe. We had, then, a pair of springs simply supporting the limbs without exerting any force against the deformity.

Since 1877 these springs have been modified by dispensing with the perineal band, and by attaching a pad at the upper end of each outer vertical bar, which pad presses against the trochanter, while force is employed against the inner side of the knee by means of a strong canvas band fastened to the outer bar and laced over the limb firmly in front.

Theoretically we have now a force acting continuously against the apex of the angle formed by the leg and thigh. And yet I do not believe that the percentage of cures is greater now than it was prior to these changes in the apparatus employed. On more than one occasion I have applied a good-fitting pair of springs in a typical case, to learn, a year or two subsequently, that they were discarded within a week, and to find the limbs straight.

Another reason for believing that spontaneous cures frequently take place is the scarcity of adult cases in this city. Comparatively few patients over ten years of age are presented for treatment, and it is seldom that one sees on our streets, go into what ward one may, an adult with this deformity.

Two years ago, while visiting nearly every part of the city in quest of old hip cases, I seldom saw a case of knock-knees in any but young children.

My own observations, I am confident, will be confirmed by the major portion of my audience. Without resorting

to statistics, I feel safe in asserting that the larger number of cases in which osteotomy has been performed, in this country at least, have been in children from three to eight years of age.

During the period I have named—viz.: from 1871 to 1877—I saw only eighteen cases in patients between fourteen and twenty-one years, and only three in patients over twenty-one years of age. Of the whole number (two hundred and seventy-six) treated, it will be seen that two hundred and fifty-five were in children under fourteen years of age. The yearly reports give fifteen of the entire number (two hundred and seventy-six) as not cured, and, on closer study, I find that this fifteen occurred in the twenty-one over fourteen years of age. Lest some one may get the impression that I assert that not one out of the two hundred and fifty-five failed to recover, I will correct the impression by stating that none were recorded as unrelieved. Statistics of dispensary cases not traced for final results are sometimes peculiarly misleading. Because a patient does not return, it does not follow, by any system of reasoning, that a cure has taken place.

This question might, however, be a pertinent one: If these patients were not restored, why do we not find many now further advanced in life presenting genu valgum?

I am therefore all the more willing to accept the statement of family practitioners that many cases of genu valgum do recover spontaneously.

Take, again, bow-legs. I am sure that many gentlemen present this evening can tell us of children whose limbs were bowed, but are now straight, without any treatment.

During the seven years immediately preceding the introduction of osteotomy for this deformity—from 1871 to 1877—I saw at the hospital one thousand and five cases of bow-legs, nine hundred and ninety-seven of which were in children under fourteen years of age. I saw only three in adults, and only five in patients from fourteen to twenty-one years of age. Many—the large proportion of the nine hundred and ninety-seven—came under treatment, and a good proportion never carried out the same. As a matter of clinical fact, their ages ranged from two to four years. Either the apparatus was very efficient, or the limbs became straight. These patients should now range from seven to ten years of age, and I think it would to-day be an unenviable task to find half as many bow-legged children between seven and ten years of age. I think I shall not be corrected if I say that the great majority of patients operated upon in this city since 1879 have been under seven years of age. Among our own people bow-legs in adults are very rare. Occasionally one does find a case in a half-grown boy or girl.

The question, then, What cases can safely be left to nature? becomes very pertinent.

1. Children under two years of age presenting bow-legs or knock-knees should not, I think, be subjected to operation or to mechanical treatment unless the deformity is very exaggerated.

2. Children under three years of age with only a moderate degree of deformity can, in my opinion, be safely left to nature. My plan is to take the outline of the deformity

on a page of my record-book; then with my hands I learn the strength of the bones, determining the springiness of the limbs. If I find the deformity slight, my advice is to defer mechanical treatment, and to bring the patient in a month or two for observation. It is seldom that I find occasion, by comparison of tracings from time to time, to employ apparatus.

In bow-legs we have often a general curve extending from the perinæum to the ankle without any sharp deviations whatever, and again there are many where the tibia and fibula are sharply curved at the junction of the middle with the lower third of the leg. In the former I rarely find it necessary to employ any form of apparatus; in the latter I rarely omit to order apparatus. In the former, nature, according to my observation, corrects the deformity so thoroughly that one can not find traces of the original deviation; in the latter, if treatment is rejected, the curve nearly always remains, and, as the child grows in height, the curve becomes longer and hence less conspicuous.

Knock-knee and bow-legs being more or less due to rhachitis, we naturally expect medication and hygiene to play a leading part in therapeutics. The general practitioner treats his cases in this way so long as the deformity is not too glaring. Rickets, being a malnutrition, calls for such drugs as will assist the digestive powers and such hygienic measures as will contribute to this end. The fact that these deformities are more common in the crowded districts of large cities furnishes an indication for rational treatment.

I know of many cases without marked bony changes cured during a season in the country. Knock-knee where it is difficult to find any antero-lateral curvature in the femora, any abnormal elongation of the internal condyle, or any elongation of the inner head of the tibia, is often corrected in apparently shorter time. Bow-legs without sharp curves in the lower third of the leg sometimes disappear completely during a sojourn in the country. A few years ago, in a discussion on rickets at the County Medical Society, I heard a distinguished surgeon from the Southwest say that there were no bow-legs in his section of the country.

The phosphates of lime and sodium are thought to have a specific action on the bony structure, and are largely administered. I have used them long and persistently, and am satisfied that their only action is on the digestion. Cod-liver oil need only be mentioned, as all men recognize this nutrient as of inestimable value.

It has been my custom to employ manual force in the correction of these rhachitic deformities under the following circumstances:

1. In patients whose parents were unable to buy apparatus and too improvident to give any attention to its care.
2. Where one has little time in which to effect a cure.
3. In cases where the bones will thus yield to such force, the other two conditions being present.

Let the following case serve as an illustration:

Last May an Italian woman, accompanied by an interpreter, brought a female child, aged four years, to my clinic, and the limbs were thus deformed:

1. Both humeri were curved forward and laterally at about the junction of the upper and middle thirds.

2. The bones of the forearm, on both sides, were bowed outward near the middle.

3. The femora presented an antero-lateral curvature near the middle, and the deformity gave rise to a marked genu valgum.

4. Both legs were bowed in the lower third, the curve being quite sharp.

In addition to the deformities already named, the spinal column presented a marked kyphosis, which disappeared on traction.

The child was eminently rachitic, and, being four years of age, demanded some surgical means of relief. The patient's address was given as in the Italian quarter in Baxter Street. Had I wished to employ apparatus, I saw no way of securing it, were it ever so inexpensive. The bones, I found, would yield considerably when I tested them with my hands.

Accordingly, on the 17th of May, at the Polyclinic, I easily made simple fracture under chloroform, with manual force, of the following bones: Tibia and fibula, on both sides; both femora; radius and ulna on the right side. Green-stick fractures were made of the right humerus, left humerus, and radius and ulna on left side. The whole operation occupied about ten minutes. Bored cotton was applied smoothly about the limbs after the deformity was corrected, and plaster-of-Paris bandages served as retentive splints. I ordered an opiate, and the child was banded up well and taken home late in the afternoon. Next day Dr. Thomas Stone, of my clinical staff, went to the address in Baxter Street and learned that the child lived in New Jersey, whence it had been taken early that morning. On the second day he succeeded in finding the family, and, barring a little oedema of the hands and feet, the case was doing surprisingly well. The rectal temperature was 98°6'.

On the seventh day I removed the plaster dressings from the lower limbs for inspection, and found the deformity not entirely overcome on the right side, while that of the left side had entirely disappeared. It required very little force to straighten the right limb. Fresh plaster was applied, and on the 21st of June all dressings were removed. During all this time, and subsequently, cod-liver oil and the compound syrup of hypophosphites were administered at the usual intervals. The child grew fat, and continues under observation, but at present I find that the thighs in their upper portion present quite a sharp antero-lateral curvature, and the arms present a moderate degree of deformity. My error was in not carrying my splints above the hips. I have accordingly had made a very simple modification of the wire cuirass—viz.: a double hip-splint, originating in the Boston hospitals—and I propose to correct the deformity of the thighs again, and retain the good position secured.

During the summer I also corrected, by manual force, a case of bow-legs in a two-and-a-half-year-old child at the Nursery and Child's Hospital. In this case the deformity was in the lower third of the leg, and it was important to afford relief in less time than splints would require.

(To be concluded.)

The American Rhinological Association.—At the recent annual meeting, the following-named gentlemen were elected officers for the coming year: Dr. P. W. Logan, of Knoxville, Tenn., president; Dr. Allen De Vilbiss, of Fort Wayne, Ind., first vice-president; Dr. J. A. Stucky, of Lexington, Ky., second vice-president; Dr. Charles A. S. Sims, of St. Joseph, Mo., secretary and treasurer.

THE HYDROCHLORATE OF COCAINE

AS A

LOCAL ANÆSTHETIC IN OPHTHALMIC SURGERY.*

By CHARLES STEDMAN BULL, M. D.

THERE has very recently been brought to our knowledge a new local anæsthetic agent, the hydrochlorate of cocaine, which within certain limits has proved of very great value in ophthalmic surgery. Our first knowledge of the effects of the drug on this side of the Atlantic came in a letter from Dr. H. D. Noyes, of this city, to Dr. E. R. Squibb, of Brooklyn, and dated Kreuznach, September 19th. An open letter from Dr. Noyes to the "Medical Record," dated September 19th, from Heidelberg, was published in the issue of the "Record" of October 11, 1884. In this letter he describes the effects of the drug upon the cornea and conjunctiva of patients, as demonstrated at the Heidelberg Ophthalmological Congress in September last. It is not the intention of the writer of this paper to discuss the origin, nature, or physiological properties of the drug, except from a clinical standpoint. Let it suffice to say that cocaine is the alkaloid made from the leaves of *Erythroxylon coca*, a shrub which grows wild and is extensively cultivated in certain portions of South America. The leaves resemble those of the Chinese tea-plant, and have been used for a great many years as a nerve stimulant by the natives of Peru and Bolivia, especially by those dwelling upon the slopes of the Andes. The alkaloid was first isolated in 1855, but its physiological properties were not thoroughly analyzed until Lössen investigated the subject in 1860 or 1861. The value of its anæsthetic properties was not recognized in ophthalmic therapeutics until the present summer, when a young medical student named Koller, at Vienna, having seen its beneficial anæsthetic effects upon the sensitive mucous membrane of the larynx, applied it to the eye and produced a superficial transient but complete anæsthesia of the cornea and conjunctiva. He brought it to the notice of Dr. Brettauer, a well-known ophthalmic surgeon of Trieste, who communicated it to the Ophthalmological Congress at Heidelberg. Through the kindness of Dr. E. R. Squibb, of Brooklyn, the writer was furnished, on October 7th, with a small supply of a two-per-cent. and a four-per-cent. solution of the salt, made from Merck's crystals, and all the physiological experiments which form the basis of this paper were made with these preparations. These experiments may be classed under three heads: 1. Experiments as to the anæsthetic effects of the drug on the sensory nerves of the cornea and conjunctiva; 2. Experiments on the pupil; 3. Experiments on the accommodation.

The drug was for the first time employed in this country as a local anæsthetic on the eye by the writer, on October 8th, in his office, for the removal of a cinder from the cornea.

1. The effects of the drug in producing anæsthesia of the cornea and conjunctiva are complete and positive, though the diminution of sensibility varies in different persons.

* Read before the New York State Medical Association, November 19, 1884.

The writer has used the drug in more than one hundred and fifty cases, and has succeeded in producing complete anaesthesia in all but three cases, while in these three cases the sensibility was decidedly diminished. When a two-per-cent. solution is used, the diminution of sensibility begins within the first three minutes after the first instillation, and the anaesthesia is complete within fifteen minutes, and usually within ten minutes. It begins to diminish in about twenty minutes, and has disappeared in from thirty to thirty-five minutes. If a second instillation is made, the anaesthesia comes on more rapidly and lasts longer, sometimes extending over an hour. When a four-per-cent. solution is used, the diminution of sensibility begins sometimes within the first minute, the anaesthesia becomes absolute within ten minutes, and, if a second instillation is employed within two or three minutes of the first instillation, the anaesthesia is complete within five or six minutes, as may be shown by rubbing the point of a probe over the cornea and conjunctiva. The instillation of neither of these solutions produces the slightest pain or discomfort, nor does it leave any lasting effects. There is no change produced in the appearance of the cornea or conjunctiva, nor is there any ophthalmoscopic evidence of any effect produced upon the intra-ocular circulation. The question whether the anaesthesia extends more deeply and affects the deeper tissues of the eye will be answered when we come to discuss its usefulness in ophthalmic surgery.

2. The effects upon the pupil. The mydriatic effect of cocaine appears much more slowly than that of atropine, and disappears more rapidly. The pupil usually begins to dilate within fifteen minutes after the instillation of a two-per-cent. solution, and within eight minutes after the instillation of a four-per-cent. solution. It increases slowly in size—in some cases very slowly; reaches its maximum in from thirty-five to forty-five minutes and then slowly diminishes, its contraction being much slower than its dilatation. In no case has the writer seen the pupil become as dilated under its use as it does from atropine, even when a four-per-cent. solution has been used. In some cases there was still a trace of dilatation on the day following the experiment. In one case no dilatation of the pupil was produced after repeated instillations of the stronger solution, though atropine acted promptly on this patient.

3. The effects upon the accommodation. The results here are, to the mind of the writer, still unsatisfactory, and require further careful observation. The range of accommodation is shortened, and the near-point does recede from the eye, even when a two-per-cent. solution is used. In the person of the writer, whose refraction is myopic, the shortening of the range of accommodation was equal to about D. 5, which came on within twenty minutes after one instillation of a four-per-cent. solution. In most of the cases in which this effect was noted the recession of the near-point began within twenty minutes after the instillation, continued to increase during fifteen or twenty minutes, and then almost immediately began to diminish, and within an hour and a half the range of accommodation was again normal. The effects of the drug are thus seen to be less marked and more transient on the ciliary muscle than on the

iris. The degree to which the accommodation was affected varied very much in different patients. Hence these observations upon the effects of cocaine on the accommodation need to be carefully repeated on a much larger number of patients before satisfactory conclusions on this head can be reached. In no case was there complete paralysis of accommodation produced.

We now come to the most important point for ophthalmic surgeons—viz., the usefulness of the drug as a local anæsthetic in operations upon the eye. The points to be settled are two: 1. Are the anæsthetic effects of the drug, when dropped upon the cornea and into the conjunctival *cul-de-sac*, merely superficial, involving only the surfaces of these membranes, or do they extend through the coats of the eyeball, merely requiring more time to produce their effects. 2. If the former, can these effects be made to extend more deeply by injecting a few drops of the solution within the cornea or beneath the conjunctiva? The writer believes that the drug is absorbed, and that osmosis does occur, but very slowly and unsatisfactorily, even when a strong solution is employed, and the anæsthetic effect upon the iris and deeper tissues of the eye is but slightly marked. But the anaesthesia of these highly sensitive membranes may be readily produced, in cases where it is necessary, by instilling a drop or two of the solution into the anterior chamber through the wound, and an operation for squint may be made absolutely painless by injecting a few drops through the conjunctival wound into the sheath of the tendon. The following *résumé* of a number of cases in which the cocaine was instilled, preliminary to operation, will give a clear idea of the extent to which it may be employed in ophthalmic surgery, and what are the limits of its usefulness.

I.—The first case in which the writer employed the drug was a bad case of abscess of the cornea, with iritis and hypopyon, occurring in an enfeebled woman aged fifty-four. Sæmisch's operation of splitting the cornea was necessary, and, after two instillations of two drops of a two-per-cent. solution, with an interval of ten minutes between them, the conjunctiva was seized with the forceps and the cornea split transversely just below the horizontal meridian, without causing the slightest pain.

II.—A case of kerato-iritis with hypopyon, occurring in a man aged thirty-five. After two instillations of a two-per-cent. solution, with an interval of eight minutes between them, the anterior chamber was opened below by a broad paracentesis through the cornea, made with a lance-knife, and the pus was evacuated, without causing the patient any pain.

III.—A case of convergent squint with hypermetropia, occurring in a young girl aged seventeen, in which it was necessary to divide both internal recti muscles simultaneously. Two drops of a two-per-cent. solution were instilled into each eye, and, after an interval of five minutes, two drops more were used. After a second interval of five minutes the conjunctiva was seized over the insertion of the right internal rectus and divided *painlessly*; but the moment an attempt was made to open the sheath of the tendon the patient winced and cried out, and expressions of pain continued for some time after the tendon was divided. In the left eye, after the conjunctiva was opened, two drops of the same solution were instilled beneath the conjunctiva, and, five minutes later, two drops more; and within ten minutes the internal rectus muscle of this eye was divided absolutely painlessly.

IV.—A case of leucoma corneæ, in a man aged eighteen, where it was necessary to perform an iridectomy for optical purposes. After the usual double instillation of a two-per-cent. solution there was complete anæsthesia of the cornea and conjunctiva, and the preliminary incision was made through the sclero-corneal margin on the nasal side *without pain*. The moment, however, the iris was seized with the forceps, the patient complained of the pain, and continued to do so until after the operation was completed. This showed that the anæsthetic effect of a two-per-cent. solution, instilled in the manner described, had not at that time extended to the iris.

V.—A case of simple chronic glaucoma in one eye, with absolute glaucoma and cataract in the other eye, occurring in a woman aged fifty-five. A two-per-cent. solution was instilled once into the first eye, and after five minutes a second time. In ten minutes after the first instillation complete anæsthesia of the cornea. The preliminary incision was made in the limbus upward with a broad lance-knife. Then two drops of the same solution were dropped through the wound into the anterior chamber, and in ten minutes a broad iridectomy was completed without the slightest sensation of pain being felt by the patient.

VI.—A case of ordinary senile cataract, occurring in a man aged fifty-six, in whom a preliminary iridectomy with massage of the cornea, known as Förster's operation for maturing cataract, had previously been done. A two-per-cent. solution was used in the ordinary manner, with complete anæsthesia of the cornea in ten minutes, and peripheral incision, quadrilateral capsulotomy, and extraction of the cataract, with ease and entire absence of pain.

VII.—A case of senile cataract, occurring in a man aged seventy-four, of excessively nervous temperament and gouty constitution. In this case a four-per-cent. solution was used, and in twelve minutes the peripheral incision, iridectomy, capsulotomy, and extraction of the cataract were all done painlessly.

VIII.—Another case of cataract, occurring in an old woman aged eighty-two. Here a preliminary iridectomy with massage of the cornea was done within fourteen minutes after the first instillation, and within six minutes of the instillation of a four-per-cent. solution within the anterior chamber.

IX.—A case of retention-cyst of the ocular conjunctiva, occurring in an elderly woman. It was as large as a Lima-bean, and hung down from the upper *cul-de-sac* over the eyeball. A two-per-cent. solution was instilled twice, and within twelve minutes the cyst was slit up, its contents evacuated with the spoon, and its inner surface cauterized with tincture of iodine—all painlessly.

X.—A case of mucocele with stricture of the nasal duct of long standing, occurring in a woman aged thirty-four. A four-per-cent. solution was instilled through the lachrymal punctum, and in eight minutes the canaliculus was slit and the sac opened, and contents evacuated. Two drops of a four-per-cent. solution were then dropped into the duct through the opening in the lachrymal sac, and in ten minutes the stricture was thoroughly divided with a Stilling's knife, and a large-sized Theobald's probe introduced—all painlessly.

It may thus be seen that almost all the various operations done upon the eyeball and inner surface of the eyelids, and on the tear-passages, may be performed painlessly under the anæsthetic influence of cocaine. The only operation on the eyeball in which it may not answer its purpose is that of enucleation; and even in such an operation, excessively painful as it is from the large number of the ciliary nerves involved, it may be possible, by a careful injection of a four-

per-cent. solution beneath the conjunctiva and within the fibrous capsule of the eyeball, to bring about anæsthesia even of these deeper nerves, and thus make the operation a painless one. Looked at even from the most unsatisfactory standpoint, and without the glamour of a very excusable enthusiasm, the drug is a most valuable addition to the resources of ophthalmic surgeons, and relieves us, to a marked degree, from the thralldom of ether and chloroform. It may seem strange to the older members of the profession to hear such an expression as "relief from the thralldom of ether and chloroform," as scarcely forty years have elapsed since Morton first employed ether to relieve the pain of any operation. But to the ophthalmic surgeon the time necessarily occupied in complete etherization, the enormous engorgement of the ocular blood-vessels produced by the ether, the danger of vomiting which may occur at any stage of an operation, and the fact that almost any apparatus for producing anæsthesia by inhalation is in the way of the operator upon the eye, are all such serious objections that *any* degree of enthusiasm in the interests of a drug which certainly releases us from such a thralldom may well be pardoned. In plastic operations about the eyelids the drug has not been tried, and, owing to its very slight effect in diminishing the sensibility of the skin, it would probably prove of little avail. A four-per-cent. solution has proved very useful in the writer's hands in certain operations upon the membrana tympani and middle ear. Paracentesis of the drum-membrane has been performed three times with entire absence of pain. In one case of exuberant granulations springing from the external surface of the drum-membrane and the auditory canal in the immediate vicinity, after one instillation of a four-per-cent. solution, these granulations were removed with a sharp scoop without causing any pain.

The action of the drug upon the swollen mucous membrane covering the nasal septum and turbinated bones, in cases of acute coryza, is very marked. The writer has used it in his own person, when suffering an attack of acute naso-pharyngeal catarrh, with almost complete occlusion of both nostrils. A probe covered with cotton was dipped into a four-per-cent. solution, and the entire surface of the septum and turbinated bones, as far as could be reached anteriorly, was painted with the solution. The same was also applied on a brush through the mouth to the posterior nares, and with such effect that in less than ten minutes both nostrils were entirely free, and remained so for about five hours. The swelling then returned, but to a less degree.

EULACHON OIL.

By E. L. SHURLEY, M.D., DETROIT, MICH.,

PROFESSOR OF LARYNGOLOGY AND CLINICAL MEDICINE IN DETROIT MEDICAL COLLEGE, ETC.

EULACHON, or "candle-fish" oil, which is said to have a local reputation about British Columbia as an efficient medicinal agent in the treatment of pithisis and other wasting diseases, bids fair, according to my limited experience with it, to become a rival of that well-established remedy, cod-liver oil. For a description of its physical and chemi-

cal properties I will refer the reader to the clear, able article of Dr. A. B. Lyons, which was published in the "Therapeutic Gazette" for September, 1884. It seems from this report that, while eulachon oil, in many particulars, resembles closely cod-liver and other fish-oils, it contains besides a substance—analogueous to paraffin—which is not found in cod-liver oil. Whether or not this substance gives the remedy a particular advantage over the other agents of its class is yet a matter of conjecture. I have been using it since about last July with very good results in twelve cases of phthisis pulmonalis of different sorts. Seven of these were hospital cases (at St. Mary's), and five were cases in private practice.

CASE I was ordinary chronic phthisis, well into the third stage. The patient had been unable to take cod-liver oil even in small doses, excepting in an emulsion; but could retain, without any difficulty, two or three teaspoonfuls of eulachon oil, two or three times a day, administered in a little whisky. The disease, however, progressed, and no signal result was noticed excepting the ability of the patient to retain the oil, and digest it.

CASE II was a well-advanced case of "grinder's phthisis," in which there was considerable consolidation in both lungs, with marked hectic fever, abundant expectoration, and rapidly progressing emaciation. Hemoptysis on April 24th to 26th, 1884. At first the eulachon oil was not retained, but, after two or three trials, there was no difficulty experienced, and the patient has been taking it since the 19th of last July, and is evidently holding his own very well, since the pulmonary tissue is not much broken down, and he thinks of resuming work. He has no hectic fever now.

CASE III was local tuberculosis of the right lung in a decorator, who had been affected for about eighteen months (following a pneumonia) with progressive emaciation; a moderate hectic fever; expectoration not very abundant; and general strength gradually declining. The eulachon oil was commenced with this patient the latter part of July, and he has been taking it since, together with tonic treatment, on and off, up to this time, with no apparent disturbance of the stomach or bowels. The temperature is still above normal, digestion is good, and the patient's strength has not declined during the last month. Nocturnal sweating is only occasional, whereas in August it was almost constant.

CASE IV was a case of bronchial phthisis of eighteen months' duration. Considerable febrile movement at night only; occasional nocturnal sweating; considerable thickening of the peribronchial tissue in both lungs; and occasional hæmorrhages. The patient had been treated with cod-liver oil before coming to the hospital, and avowed his inability to take anything of the sort. The eulachon oil was administered, first in half-teaspoonful doses, the patient having been assured that it was not cod-liver oil, and the dose gradually increased to a tablespoonful three times a day, which he has taken up to this time, with occasional doses of cinchonidine and anodynes to allay cough. Up to the 20th of October, when last seen, he had gained three pounds in weight since August 2d, experienced no difficulty in retaining the oil, and is apparently improving.

CASE V.—A machinist, who had resided up to last July in Connecticut, had been affected with cough for the last two years, and for the last nine months had rapidly declined in strength, and suffered from hæmoptysis and hectic fever. By two or three physicians at his home was advised to go to Colorado as the only chance for life. Having some relatives here, he stopped on his way, and was induced to seek advice at St. Mary's Hospital. He was very much emaciated when he pre-

sented himself in May, his pulse being very rapid, hectic fever marked, expectoration profuse, with almost constant nocturnal sweating. Has had three attacks of hæmoptysis; the last one on July 14th. Said he had taken cod-liver oil, malt, etc., before coming here, but could not take the oil more than a week or two at a time. It was found, upon close questioning, however, than oftentimes the oil was rejected, because of being taken at improper times, and on account of severe fits of coughing. This patient was treated by the administration of cod-liver oil emulsion, malt, compound syrup of the hypophosphites, etc., with no improvement up to August 15th, since which time he has steadily taken eulachon oil together with compound tincture of gentian and Fowler's solution of arsenic, until September 5th, when the gentian and Fowler's solution were stopped, and he has taken nothing but eulachon oil since (about four tablespoonfuls daily). Up to October 1st there seemed to be very little improvement in his condition; but since then he has rapidly improved, expectoration and febrile movement diminishing, no nocturnal sweating, no derangement of the bowels, and from October 10th to November 5th he has gained four pounds in weight.

CASE VI was a case of incipient phthisis of three months' duration. Very decided apex catarrh of the left side, incessant cough, great disturbance of the stomach. Gastric irritability was so great from coughing that food was often ejected. Emaciation taking place quite rapidly, but febrile movement not proportionately strong. This patient had tried cod-liver oil, but it would not digest. Eulachon oil was administered about the 15th of September, but met the same fate that had attended the ingestion of cod-liver oil. It was rejected sometimes immediately, and sometimes in the course of half an hour. It was now stopped entirely for a period of a week or two, when anodynes, malt, and stomachic tonics were prescribed. At the end of this time a 25-per-cent. emulsion of eulachon oil was administered. This, however, while it did not seem to digest, was not rejected by the stomach. Its administration was suspended for a few days again, and the stomachic tonics were resumed. In October the emulsion was again administered, and with success. For the last two weeks the patient has been taking a 50-per-cent. emulsion, with marked benefit.

CASE VII.—A case of acute phthisis. Extensive tuberculous deposit in the upper lobe of the left lung, and some at the apex of the right. Two or three small cavities. Constitutional symptoms—such as hectic fever, nocturnal sweating, rapid pulse, etc.—quite strong. Besides this, a persistent diarrhœa. With this patient cod-liver oil increased the bodily temperature, and increased the diarrhœa and anorexia, whether given pure or in emulsion. After treatment by very mild tonics, bismuth, and preparations of extracts of malt, covering a period of two weeks, a 25-per-cent. emulsion of eulachon oil was administered. This at first did not seem to agree with the stomach (although there was no increase of diarrhœa), and fishy eructations were complained of by the patient. It was now administered, and each dose followed immediately by five grains of bicarbonate of sodium, when, after a day or two, the patient was enabled to take the emulsion without complaining of disagreeable eructations. No extra disturbance of the bowels was noticed until an attempt was made to give a 50-per-cent. emulsion. However, by an occasional administration of an opiate, he was enabled to take a 35-per-cent. emulsion, which apparently agreed with him nicely, and he seemed to more than hold his own. As I have not seen him since October 25th, on account of his removal from the city, I do not know the further progress of the case. The case, nevertheless, illustrates the good effect of the oil regarding the disordered alimentary tract.

In the five cases in private practice an attempt was made to

administer the *pure oil*; but in two of the cases it was found impossible, and in one it could only be administered in the form of emulsion; while in the other one it could not be administered at all in any form, as the most persistent effort on the part of the patient as well as myself demonstrated. Of the remaining three cases, one was a case of grinder's phthisis, in a man forty-six years old, in whom an apparent arrest of the disease had taken place a year ago; but a renewal of activity began last June, when circumscribed inflammation, resulting in abscesses, very speedily followed, with consequent emaciation, hæmoptysis, and hectic fever. At the time of beginning the administration of eulachon oil, in September, the patient was confined to his house; very much emaciated; constant elevation of temperature— 101° to 103° F.; expectoration of a very large amount of sputum more or less mixed with blood; anorexia, nocturnal sweating, persistent cough, and troublesome diarrhœa. An attempt to administer the pure oil at first failed, but, after persisting for two or three days, he was able to retain and digest it. He has been taking three tablespoonfuls and a half daily since October 12th. He is now improving quite rapidly, and walks out a little every day. Besides this treatment, he has been taking tannate of quinine, with opiates, on and off, for the relief of diarrhœa, and balsamic inhalations, but at no time did I discover that the ingestion of the oil increased the alvine evacuations.

The fourth case was one of ordinary phthisis, in a female, in the second stage of its development, which seems to be doing well. She has taken the oil since about the 3d of August with very little intermission; and, although she has not gained in weight, she has only occasional hectic fever, and is able to attend to her household duties daily.

The fifth is a case of phthisis in its early stage, with a small deposit of tubercle at the apex of the right lung. Dyspeptic symptoms quite marked; bowels constipated. An evening temperature generally of 102° ; quite anæmic. This patient has been taking a 50-per-cent. emulsion of eulachon oil since the latter part of September, and no disagreeable effects follow its administration. No other medicine has been administered excepting a cough syrup consisting of codeine and syrup of tolu. No softening of the patch has yet taken place, as shown by physical exploration of the chest made a week ago. No difficulty in digesting the oil is experienced. Neither has the patient any relaxation of the bowels, excepting occasionally from eating fruit. The body-weight has increased two pounds since the beginning of the administration of the oil.

The foregoing summary seems to me to point out the fact that eulachon oil is certainly not inferior to cod-liver oil in the general run of cases. Of course, there are some patients with whom the administration of any oily substance is impossible. But, if this fish-oil proves to be more digestible and agreeable than the time-honored cod-liver oil, it should certainly receive favor on that account.

The results above given might possibly have been accomplished by cod-liver oil, but in most of the patients with whom this remedy was used it was ascertained that cod-liver oil had been administered, more or less previously. While, therefore, one would not claim, from this limited experience, that the eulachon oil is in any way a *specific* against phthisis pulmonalis, I think, however, that the clinical trial given it fairly shows its superiority in digestibility over cod-liver oil. In only one of the cases did I find that eulachon oil really produced diarrhœa, while cod-liver oil (as the majority of the profession will testify) is very prone (when used to any

extent) to cause this harassing and sometimes grave complication. Indeed, of late years, on this account, as well as because of its taste, I have used far less cod-liver oil than I did formerly, and find myself gradually coming to abandon it.

Emulsions of this oil may be made in the same way as emulsions of cod-liver oil. I generally prefer a flavoring of almond oil, with either cinnamon, wintergreen, or peppermint. The question of price is something important for the physician to consider; for any comparatively new remedy is apt to be high-priced; but I understand this oil will probably be furnished to the market as cheap at least as cod-liver oil, and perhaps cheaper. If this is so, it seems to me that its less disagreeable properties, and its equally good, if not much better, therapeutic value, will give it a great advantage over cod-liver oil, which has held for so many years such a prominent place in the physician's armamentarium.

NEW YORK, SATURDAY, NOVEMBER 29, 1884.

THE ANATOMICAL MUSEUM AS AN ELEMENT IN MEDICAL
EDUCATION.

It is generally believed that no amount of demonstration can ever impart to the student as much anatomical knowledge as he acquires by his own work in the dissecting-room. This is true for a certain class of students, and to a limited extent, but we venture to state that, as dissecting is ordinarily conducted in this country, it oftener becomes a stumbling-block than an assistance to the beginner. We would not be understood as assuming a critical attitude toward any school or system of instruction, but we simply proceed on the principle that, when anything can be learned from foreign methods of teaching, it is unwise to reject the example merely because it is foreign. Professor Wilder struck the keynote of the matter, in his Cartwright Lectures, when, speaking of the prevailing ignorance as to methods of studying the human brain, he asked, "Has it never resulted that the principal acquisition of the students has been a profound conviction of the self-confidence of the demonstrator?"

There is reason to think that the ordinary purpose of the medical student, when he takes his scalpel in hand, is either to get through with his "part" in the shortest time possible, or, with more praiseworthy zeal, to make a pretty dissection. The ultimate object of his work, the acquiring of an exact knowledge of anatomy, is entirely lost sight of by all but a small minority. A student who does not finish his "part" in a week is apt to be regarded as wanting in thirst for anatomical lore. This state of things being apparently inevitable under the system now in vogue among us—a system which limits the demonstrator's work to a mere perfunctory discharge of his duties—it remains to be asked whether the ample material which we have can not be turned to account in some other way, so that the student who can not or will not work for himself may enjoy the results of another's skill and experience. There is such a method, and it is by its systematic application that English, French, and German students gain such a thorough knowledge of anatomy.

Every English hospital, large or small, has its museum, which has been enriched by the labors of generations of demonstrators. The preparations are executed with marvelous care and fidelity, and are mounted in such a way that they can be removed easily for purposes of study. They are entirely at the student's service, and he is encouraged to take his books into the museum, sit down in some quiet corner, and spend hours in the careful, minute study of a single preparation. Thus anatomy is made for him a subject of real interest—the thoracic duct, the chorda tympani, and other structures that he would other-

wise regard as more or less mythical, seeing them only with the eye of faith, become to him living realities, for he has seen and handled them. Not one of the delicate organs of the central nervous system, or of the apparatuses of special sense, is allowed to escape his careful scrutiny. Stimulated by the study of accurate dissections, he strives to equal them. Is it surprising, then, that the English medical student frequently spends a month over a single part?

The German and French methods are only a repetition of the English—the glycerin preparations of the Vienna museum, the wonderful wax models of the Italian schools, are all designed to accomplish the same purpose, the constant and thorough drill of the student in this most important branch of the curriculum. It is unnecessary to enlarge upon the results of this method of teaching; the important question is, whether a like course is practicable in this country. So long as our museums are regarded simply as collections of antique relics, to be visited only by the curious, the first-year student will certainly never take the trouble to examine their contents critically. We have museums (a few), but not one tenth of the instructive specimens find their way into them, and as for the student's being allowed to handle those that are there, it would be regarded as a sort of sacrilege. Until we supplement our deficient demonstrations and dissecting-room work with some systematic use of the material now hidden away on the dusty shelves of museums, anatomy will continue to be, as it is now, the bugbear of the American student, rather than a subject of living interest. With the increasing resources of our medical schools, it is important that teachers of anatomy should ask themselves whether there is not an opportunity for reform in their department.

MEDICAL HEROISM.

THE British medical journals have of late contained many commendatory notices with reference to the sad death of young Mr. Rabbeth, who died from diphtheria contracted by sucking a plug of membrane out of a child's trachea. In addition to the rather excessive amount of praise which has been lavished upon the dead physician, it has been proposed to establish a gold medal in his honor at one of the medical colleges. This recalls the story of the French *interne* who contracted the same disease in the performance of his hospital duties, and was awarded the cross of the Legion of Honor, but too late, as it was placed on the breast of his dead body.

There is something in a generous, impulsive deed that stirs the most stolid heart, especially when it involves the sacrifice of a life. How often have we felt an indescribable thrill of enthusiasm on reading the familiar tablet on the wall of a college lecture-room, recording the names of medical men who died in the performance of their duty during an epidemic! The closing words, "*Hæc mea ornamenta sunt*," have inspired many a careless student with a vague longing to imitate their example.

But, while applauding solitary instances of devotion, let us not forget that the same spirit that actuated Mr. Rabbeth moves

in the breast of every true physician, or that similar acts are performed daily in all parts of the land by obscure and unknown practitioners, who court no fame, who are not even aware of the fact that they are performing a praiseworthy deed. The unsung heroes, like the "missing" after a great battle, are not few in our profession. Let us not, while raising one shining example to the skies, forget those whose devotion is unrewarded save by the "inner consciousness of work well done."

MINOR PARAGRAPHS.

TWO WELL-KNOWN WORKS ON SURGERY.

UNDER the heading "Surgical Science and Surgical Practice" the "Medical Times and Gazette" draws an interesting comparison between the new editions of Mr. Bryant's and Mr. Erichsen's works on surgery. It is always instructive to read the criticisms of the English on their own writers, especially when those writers are teachers occupying such high positions as are accorded to the authors in question. The critic in the present instance is respectful, but none the less sharp, in his comments. He starts with a declaration which is undeniable—that both the books are "exceedingly faulty, artificial, and unscientific." The wonder is that, with this plain counsel (which has been offered several times before), neither of the authors has condescended to modify his work accordingly. This is an example of English conservatism of which even Englishmen disapprove.

Listerism seems to be the rock on which Mr. Bryant has been wrecked, and, while professing to draw a comparison between the two books, the critic takes occasion to place Mr. Bryant in rather an unfavorable light. It is not to be denied that there are serious defects in his book, but surely something ought to be said of its fitness as a student's manual—for which it was always intended—when compared with the verbose and over-loaded volumes by Mr. Erichsen. It is the complaint of every English teacher of surgery, provided he has not himself written a book, that there is no surgical text-book suitable for students. If no one has sufficient public spirit to write a new treatise, it is unfortunate for the students that the old ones still retain the faults that have so often been pointed out in former editions.

SECTIONAL WORK IN THE STATE MEDICAL ASSOCIATION.

As our readers will have noticed in the report we gave last week of the first annual meeting of the Association, the question was raised of dividing the work of the meetings so that it should be done in two sections. No plan to this effect was adopted, but there seemed to be a feeling that it might prove necessary to make such an arrangement in the future. Doubtless the Council will consider this matter in all its bearings before taking any positive step, but we will venture to suggest that, whatever advantages there may be in a division into sections in so large a body as the American Medical Association, there seem to us likely to be none in the case of a compact body that will quite offset the sense of privation sure to be felt by many of the members at not being able to be present at the entire proceedings. Nearly all the Fellows of the Association are general practitioners, interested in the various branches of medicine alike, and we are much mistaken if the great majority of them would not entertain this feeling.

THE MICHIGAN STATE MEDICAL SOCIETY.

It is with much satisfaction that we have examined the last volume of "Transactions" of the society, for the year 1884,

which shows that the work of the society is quite abreast of the times. The mistake is too often made of looking upon the transactions of State societies as possessing only a local interest. Papers of great value are frequently hidden away modestly in such volumes, and the city practitioner commits a great injustice to his rural brethren when he draws the inference that the latter seek the opportunity of rushing into print without having very much to say. The fact is that the country practitioner not only runs across rare and interesting cases, but often observes and works them up with far more thoroughness than his busy (and more self-confident) metropolitan confrère.

AN ACADEMIC AFFAIRE D'HONNEUR.

BERLIN is just now agitated over a choice bit of university scandal. It seems that one Dr. Schweninger was appointed an extraordinary professor because of his success in checking the excessive growth of the German Chancellor's "fair round belly." There are certain of his colleagues who do not regard the service, distinguished as it was, as sufficiently great to entitle Dr. Schweninger to a seat in their body. The new professor called on the Rector, Du Bois-Reymond, and left his cards, which were promptly returned to him. Dr. Schweninger, instead of resorting to the scientific method of retaliation by attacking the Rector's published works, meditated vengeance upon his person, and dispatched a challenge, in true student fashion, which was at once declined.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending November 25, 1884:

DISEASES.	Week ending Nov. 18.		Week ending Nov. 25.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	32	9	42	13
Scarlet Fever.....	49	12	61	15
Cerebro-spinal meningitis....	8	8	1	1
Measles.....	83	12	127	21
Diphtheria.....	62	35	73	25
Yellow Fever.....	0	0	1	1

The New York Academy of Medicine.—At the next meeting, to be held Thursday evening, December 4th, Dr. Joseph E. Winters will read his paper on Tracheotomy in Diphtheritic Croup, which was read before the Obstetrical Section on the 23d of October. He invites discussion on the following points: 1. Is tracheotomy dangerous to life? 2. In what stage of croup should the operation be performed? 3. The causes of death after tracheotomy. 4. The influence of the operation on the disease. 5. The after-treatment.

The Illinois State Board of Health.—At the recent quarterly meeting, held in Springfield on the 20th and 21st inst., the Secretary, Dr. John H. Rauch, presented his report for the quarter ending September 30th, recounting the action taken by the board during the quarter in the matters of sanitation and the administration of the Medical Practice Act, and closing with the following recommendations and suggestions: "1. That a committee of the board be appointed to prepare revisions and amendments of the laws of the State regulating the practice of medicine and concerning the protection of the public health. The defects of the statutes concerning both these subjects are patent, and should be remedied as speedily as possible. 2. That action be taken in anticipation of the forthcoming meeting of the National Conference of State Boards of Health, with

reference to the subject of Asiatic cholera." Action was taken in accordance with these suggestions, and a practitioner's license was revoked for "unprofessional and dishonorable conduct."

The Death of Dr. Fauvel, of Paris, is announced as having taken place on the 6th inst.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 9, 1884, to November 22, 1884:*

BYRNE, C. C., Major and Surgeon. Granted four months leave of absence from November 16, 1884. S. O. 265, A. G. O., November 11, 1884.

TERMAINE, W. S., Major and Surgeon. Granted leave of absence for one month on surgeon's certificate of disability. S. O. 233, Department of the East, November 12, 1884.

WILSON, WILLIAM J., Captain and Assistant Surgeon. Granted leave of absence for four months, with permission to go beyond sea, to take effect when his services can be spared by his department commander. S. O. 262, A. G. O., November 7, 1884.

SHEFFELDT, R. W., Captain and Assistant Surgeon. Assigned to duty as post surgeon at Fort Wingate, N. M. S. O. 217, Department of the Missouri, November 4, 1884.

OWEN, WILLIAM O., JR., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Canby, Washington Territory, and ordered to Fort Spokane, Washington Territory, for duty. S. O. 169, Department of Colorado, November 4, 1884.

McKEE, JAMES C., Major and Surgeon. Leave of absence extended one month. S. O. 273, A. G. O., November 20, 1884.

GODDARD, C. E., Major and Surgeon. Assigned to duty at Fort Yates, Dakota Territory. S. O. 138, Department of Dakota, November 15, 1884.

COWDREY, S. G., Captain and Assistant Surgeon. Granted leave of absence for one month. S. O. 237, Department of the East, November 17, 1884.

HAYARD, VALERY, Captain and Assistant Surgeon. Granted leave of absence for four months. Permission to go beyond sea. To take effect when his services can be dispensed with at his present station. S. O. 268, A. G. O., November 14, 1884.

TAYLOR, A. W., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Omaha, Neb., and ordered for duty at Fort D. A. Russell, Wyoming Territory. S. O. 101, Department of the Platte, November 19, 1884.

PHILLIPS, JOHN L., First Lieutenant and Assistant Surgeon. Assigned to duty at Fort Keogh, Montana Territory. S. O. 134, Department of Dakota, November 5, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the two weeks ending November 22, 1884:*

BEARDSLEY, GROVE S., promoted to the grade of Medical Inspector, April 24, 1884. November 14, 1884.

HEFFENGER, A. C., Passed Assistant Surgeon. Assigned to duty at Portsmouth, N. H., to continue till December 12, 1885. November 11, 1884.

WIEBER, F. W. F., Assistant Surgeon. Ordered to the receiving ship Vermont, at New York, November 12, 1884.

AMES, HOWARD E., Passed Assistant Surgeon. Detached from the Greely relief steamer Bear, and assigned to special duty in New York. November 17, 1884.

BRIGHT, GEORGE A., Surgeon. Detached from the Galena and placed on waiting orders. November 19, 1884. daigua, N. Y.

CLEBORNE, C. J., Medical Inspector. Assigned to duty at Philadelphia, Pa., as member of Medical Examining Boards. November 21, 1884.

DU BOIS, F. L., Surgeon. When detached from the Naval Examining Board, November 29th, is ordered to the Galena. November 20, 1884.

GREEN, EDWARD H., Passed Assistant Surgeon. Detached from the Greely relief steamer Thetis, and assigned to special duty in New York. November 17, 1884.

HALL, J. H., Surgeon. Detached from Navy Yard, Mare Island, and assigned to duty at the Naval Hospital at that yard. November 19, 1884.

HUGG, JOSEPH, Surgeon. Assigned to the Minnesota as relief of Surgeon Woolverton. November 15, 1884.

MARTIN, WILLIAM, Assistant Surgeon. Ordered to special duty in connection with the New Orleans Exposition. November 19, 1884.

NASH, F. S., Passed Assistant Surgeon. Detached from the Greely relief steamer Alert, and assigned to special duty in New York. November 17, 1884.

SIMON, W. J., Surgeon. Ordered to the Philadelphia Hospital for treatment. November 17, 1884.

WOOLVERTON, T., Surgeon. Detached from the Galena, and placed on waiting orders for sea service. November 15, 1884.

Society Meetings for the Coming Week:

MONDAY, December 1st: Medico-Chirurgical Society of German Physicians of New York; Morrisania Medical Association, New York (private); Brooklyn Anatomical and Surgical Society (private); Utica, N. Y., Medical Library Association; Boston Society for Medical Observation; Providence, R. I., Medical Association; Hartford City, Conn., Medical Society.

TUESDAY, December 2d: New York Obstetrical Society (private); New York Neurological Society; Elmira, N. Y., Academy of Medicine; Buffalo Medical and Surgical Association; Ogdensburg, N. Y., Medical Association; Medical Societies of the Counties of Herkimer and Saratoga, N. Y., and Hudson, N. J.

WEDNESDAY, December 3d: Medical Society of the County of Richmond, N. Y.

THURSDAY, December 4th: New York Academy of Medicine (Nominations of Officers; Paper by Dr. Joseph E. Winters, entitled "Is the Operation of Tracheotomy in Diphtheritic Croup Dangerous? When should the Operation be Performed?"); Society of Physicians of the Village of Canandaigua, N. Y.; Boston Medico-Psychological Association.

FRIDAY, December 5th: Practitioners' Society, New York (private).

SATURDAY, December 6th: Manhattan Medical and Surgical Society, New York (private); Miller's River, Mass., Medical Society.

Letters to the Editor.

HYDROCHLORATE OF COCAINE IN MINOR SURGERY.

SOUTH NORWALK, CONN., November 22, 1884.

To the Editor of the *New York Medical Journal*:

SIR: As a contribution showing the efficacy of hydrochlorate of cocaine in minor surgery, the following case is of interest at the present time:

A. B., a phlegmatic German, about forty years of age, on Friday, the 14th inst., while cleaning a revolver, accidentally shot himself in the

right hand. The ball (.22 caliber) entered the palm of the hand opposite the third carpo-phalangeal articulation, and, passing outward under the flexor tendons of the hand, lodged against the first phalanx (inner surface) of the little finger, about half an inch in front of the articulation with the corresponding bone. Twenty-four hours after the accident the man came to my office to have the wound dressed. At that time the hand, which naturally was very large and thick, was considerably swollen and inflamed; there was also considerable pain. I gave him a hypodermic injection of five minims of a two-per-cent. solution of the hydrochlorate of cocaine on the back of the hand, at the inner side of the last metacarpal bone—deeply injected, so as to bring the drug as near as possible to that branch of the ulnar nerve supplying the inner side of the little finger. Five minutes later another hypodermic of the same amount was given along the back of the first phalanx of the little finger, the solution being thrown in as the needle was withdrawn. He said that the introduction of the needle the second time gave not the slightest pain, the first one having hurt him and been followed by smarting (probably due to the alcohol). After waiting five minutes longer, I made the necessary incision, an inch or an inch and a half long and quite deep, owing to the size of his finger and its swollen condition. Neither the cut nor the subsequent manipulation in the removal of the ball, nor the dressing, gave him *any pain whatever*. He described his sensations in the hand as being "numb or asleep."

Without the cocaine, the little operation would have been quite painful, owing to the inflamed condition of the parts. I have performed two or three other slight operations upon mucous membranes, where the drug was applied on a pledget of cotton soaked in the solution, held against the part for ten or fifteen minutes, which were equally painless.

Yours sincerely,

W. C. BURKE, JR.

HYDROCHLORATE OF COCAINE IN DERMATOLOGICAL PRACTICE.

14 EAST THIRTY-FIRST STREET, November 24, 1884.

To the Editor of the *New York Medical Journal*:

SIR: Much has been published of late concerning the local anæsthetic effect of the hydrochlorate of cocaine, mainly by the ophthalmologists. It is from the dermatological standpoint that I wish to make this contribution.

Epilation by means of electrolysis is often, to some patients, rather a painful procedure, especially about the upper lip, near the nose, and over the jaw bone, between its angle and the chin. These regions offered a good field for testing cocaine. Accordingly, I had a four-per-cent. ointment of cocaine and oleic acid (not an oleate, you will perceive) made by my druggist, Mr. Fingerhut, of No. 404 Fourth Avenue, the hydrochlorate used being from a lot that had proved active in ophthalmological practice. I first tried it on the back of one of my wrists, rubbing it in for some five minutes. I found that pulling on the hairs of the part rubbed was much less painful than elsewhere. Then I had an intelligent patient, whose superfluous hairs I was removing by electrolysis, rub it well into the left side of her upper lip and into her cheek, between the angle of the jaw and the chin. In about five minutes the anæsthetic effect was well marked, and she allowed the hair in those regions to be extracted with a current from twelve cells of a freshly charged battery without evincing any signs of pain. Two days before, the operation had been very painful, although only nine cells were used, and on the same day the corresponding regions on the other side of the face were very sensitive. The anæsthetic effect lasted for the whole time I was working, probably thirty minutes. The patient said that some hairs were removed without her feeling it, and that the pain attending the extraction of the others did not amount to anything.

One case is not much to build upon, and I only report this

to encourage others to try cocaine in similar cases. I certainly feel encouraged to try again.

Yours,
GEORGE THOMAS JACKSON.

A POINT ON LIGATURES.

INDIANAPOLIS, IND., November 1, 1884.

To the Editor of the *New York Medical Journal*:

SIR: I recently sewed up a bad cut on a boy's hand with one of the three strands of ordinary surgeon's silk, unwaxed and not antiseptised, purposely. In four days there was nothing unabsorbed but the knot. Dirt and air were excluded by two layers of silk isinglass plaster.

I removed an egg-sized adipose submaxillary tumor, a few weeks ago, through a three-inch incision. The wound was closed with clean, new, $\frac{3}{8}$ surgeon's silk, without plaster or external application of any kind, the suture material unwaxed or otherwise treated. The lips of the external wound were perfectly united, without a drop of pus about the wound, and the *subcutaneous part of the ligatures was almost gone from absorption* on the fifth day, when the knots were removed. Silk is formed animal tissue, and, without being rendered a foreign body by wax or other treatment, may be the much needed ligature we seek. My opportunities for testing this matter are so limited I ask you to use the hint (if you think best), since I find several good surgeons here have not heretofore appreciated the point, as possibly some of your distinguished experimenters have.

Truly yours, L. D. WATERMAN, M. D.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

Meeting of November 11, 1884.

The President, Dr. ROBERT F. WEIR, in the chair.

Simultaneous Incomplete Wound of the Femoral Artery and Vein; Ligation of both Vessels in the Wound; Recovery.—Dr. L. S. PILCHER presented a man, aged thirty-four, a butcher, who, in the evening of May 17th last, accidentally stabbed himself with a sharp, long, narrow-bladed knife, the blade entering the upper and front part of the right thigh, a little below the line of Poupart's ligament. The overwhelming hæmorrhage which at once followed was fortunately quickly controlled by pressure at the hands of Dr. N. B. Sizer, of Brooklyn, who happened to be within hail at the moment of the accident. This pressure was then assisted by the insertion of a tampon into the wound until the arrival of Dr. Pilcher, and thus time was afforded to make the necessary arrangements for the permanent arrest of the hæmorrhage. The parts adjacent to the wound were shaved and cleansed, and as full an effort was made to conduct the required operative procedures without septic contamination as was possible under the circumstances. The original wound was a transverse cut of only three fourths of an inch in extent. A longitudinal incision of some inches in length was made, extending above and below the stab cut, while pressure was kept up at the point from which hæmorrhage proceeded. The femoral vessels in Scarpa's space having been fully exposed, it became evident that the knife had pierced the femoral vein about an inch and a half below Poupart's ligament, and, having divided its outer half, had also divided the adjacent inner half of the femoral artery, inflicting thus an incomplete wound upon both the main vascular trunks of the limb. While pressure was still directed upon the vein wound, the artery, being compressed above, was completely divided at the point of

wound, and each of the divided ends secured by a catgut ligature. More difficulty was experienced in dealing with the vein, for, although adequate pressure was made upon it both above and below the wound, the moment the pressure upon the wound itself was interrupted, a most copious flow of blood would deluge the field of operation. The embarrassments of the moment were increased by the dim light, which was but little bettered by the lamp of the ambulance surgeon who was acting as one of Dr. Pilcher's assistants, and by the fact that the previous infiltration of the region with blood had become such as decidedly to obscure the distinctions between the tissues of the parts usually available as guides. Further dissection, however, finally revealed two large muscular vein-trunks entering the femoral vein from behind, just opposite the point of the wound. A ligature having been tied about each of these, the further dealing with the main trunk, by severing it and tying each end separately, was accomplished without difficulty. The wound was then irrigated with solution of bichloride of mercury, 1 to 1,000, and closed with sutures, proper bandaging and compresses being applied to insure union by first intention. Suppuration, however, took place, and on the third day the wound was reopened at its most dependent point, drainage-tubes were inserted, and irrigation was resorted to. A sharp attack of cellulitis along the line of the sartorius muscle followed, making several counter-openings for drainage necessary for its control.

The patient rallied well from the extreme loss of blood sustained at the time of the accident. After the eighth day his progressive convalescence was assured. His perfect recovery was delayed by the fact that some of the catgut ligatures proved to be irritants, and determined circumscribed phlegmons at the points where they had been applied. These all finally closed, and on the 2d of July the patient began to attend to his business again. Later in July another small phlegmon formed at the site of the lower ligatures, which, however, occasioned only a temporary inconvenience.

At no time in the history of the case did any noticeable disturbance in the nutrition of the limb occur. In the early days, after he began to walk about, there was marked oedema with weakness of the leg; an elastic stocking sufficed to control this. To-day, about six months after the injury, he used no support to the limb, and impaction showed a barely recognizable tendency to oedema of the leg. During the operative procedures required for ligating the vessels at the time of the injury, neither the profunda artery nor the internal saphenous vein came into view, but it might be assumed that the wounds were below the points where these vessels joined their respective main trunks.

Besides the interest attaching to the peculiar nature of the wound itself, and the fortunate conjuncture by which immediate death was averted, special interest attached to the bearing of the case upon the treatment of wounds of the femoral vein. The history of the case demonstrated the value of diminishing the arterial supply to the limb, when the great vein outlet of the limb had been secluded, but, as a means of controlling the hemorrhage from the vein wound, it had been seen that the ligation of the femoral artery was valueless, for the apparent profuseness of the flow from the vein wound was not diminished after the artery had been secured.

Dr. A. G. GERSTER reported a case which occurred in his experience five years ago, and belonged to the class of injuries included in Dr. Pilcher's case. One of his colleagues at a city hospital had removed the inguinal glands from a young man. It was thought afterward that, instead of an eight-per-cent. solution of chloride of zinc being used, by the mistake of a nurse a much stronger solution was employed for washing out

the wound, at the bottom of which the femoral vein and artery were exposed. Three days after the operation an exceedingly profuse hemorrhage occurred, and the house surgeon knew no better than to throw an elastic bandage around the limb below the point of bleeding, because it was venous blood which poured out of the wound. The constriction was sufficiently strong to compress the veins but not the artery, and the limb became a reservoir for a large collection of the patient's blood. Accidentally Dr. Gerster called at the hospital about two hours after this had occurred. When his attention was directed to the case he saw that local pressure was being kept up by means of large bundles of dry cotton pushed into the bottom of the wound. Naturally, it failed to control the hemorrhage completely. The patient was nearly dead from acute anæmia. Dr. Gerster removed the clots from the bottom of the wound, for the purpose of finding the source of hemorrhage, and saw that a piece about one inch long and one fourth of an inch wide, belonging to the anterior wall of the vein, had sloughed out, and through this large opening great quantities of blood poured forth. The artery being exposed in the bottom of the wound, his first thought was to adopt Langenbeck's proposal to occlude the femoral artery, which was easily accomplished by pressing it against the pubes. But this did not control the hemorrhage, wherefore the idea of ligating it was abandoned. There remained, therefore, nothing but to ligate the vein itself, and he divided the vessel as Dr. Pilcher had described, as well as possible while pressure was being constantly exerted upon it above and below, and applied ligatures on both ends. The hemorrhage, however, did not cease, and continued because large muscular, venous trunks entered from behind. By the time these were exposed and tied the patient had expired. Undoubtedly it was not external hemorrhage alone in this case which caused the fatal issue, because one of the largest limbs of the patient was gorged with blood to its utmost, and was not only cyanosed, but was necessarily increased in circumference.

Aneurysm of the Right Subclavian Artery.—Dr. GERSTER then presented a patient with the following history: Aug. Beute, fifty-one years old, a cigar maker by trade, never had syphilis, and, no vestiges of the disease being visible, presented a large, bony frame covered by wasted, flabby muscles, and a pale, sallow skin. He alleged that he had noticed increasing and very acute pain along his right arm since the summer of 1883, accompanied by wasting of the muscles and a peculiar bluish discoloration of the skin of the arm and hand. Since autumn the terminal phalanges on the right hand had become shovel-shaped, the nails like claws, and his general condition very much impaired by constant pain, fornication in the hand; and lately there had been increasing dyspnoea. Shortly before New Year's, 1884, Dr. John Schmidt noticed, at the German Dispensary, a pulsating tumor behind and to the right of the sterno-clavicular joint of the right side, and diagnosed an aneurysm of the right subclavian artery. Dr. Gerster confirmed the diagnosis, but thought that the location of the tumor, the pulsatile elevation of the sterno-clavicular joint, a corresponding dullness, and the dyspnoea, warranted the assumption that the aneurysm at its bifurcation was also concerned in the lesion. The characteristic *bruit* was present, and the carotid and radial pulses were normal and synchronous with the heart's action. The inferior cervical triangle of the right side presented not a depression, but a distinct elevation above the level of the clavicle and the sterno-mastoid muscle, the main swelling and resistance being probably situated in the angle of the clavicle and the sterno-mastoid muscle. Direct pressure on the tumor was not tolerated, on account of the intense pain, but reduced the swelling and pulsation to a great extent.

On January 16, 1884, Dr. Gerster ligated the common carot-

id and the subclavian, or, according to English nomenclature, the axillary artery, the latter being tied in Mohrenheim's triangle, below the clavicle. The ligatures used were of juniper catgut. The incisions were sewed up, not drained. Immediately after the ligatures were applied the radial pulse and that of the carotid disappeared, but the pulsation of the tumor became more violent than before, when the ligature on the carotid was tightened. Nothing abnormal was observed regarding the pupils, the heart's action, or the respiration.

For a considerable period of time no appreciable difference in the conformation of the pulsating swelling was observed, and, on the contrary, the shooting pains and formication along the branches of the brachial plexus seemed to increase. The wounds healed correctly under a single dressing. About four weeks after the operation it first became apparent that the tumor had decreased in size. Simultaneously the pains became more tolerable. In March and April thirty hypodermic injections of Bonjean's ergotin were made in the abdominal region, and seemed to hasten the shrinking of the tumor, which now became very manifest. By May the cyanosis, hyperidrosis, glossy skin, and formication, as well as the neuralgic symptoms, had so much abated that the patient could sleep without opiates, and had gained over ten pounds in weight. The atrophy of the muscles of the arm and forearm had also improved materially under massage and active exercise, and now the patient, who had seemed to be at death's door, might be said to be fairly and sufficiently comfortable, and was attending to his avocations. The abnormal pulsation and *bruit* had entirely disappeared, and only a well perceptible fullness and resistance could be seen and felt in the right supraclavicular fossa as compared with the other side. There were short, mild, and rare attacks of shooting pains along the arm and up the nape of the neck; and finally, the peculiar shape of the terminal phalanges of the hand and of the nails of the right hand had unavoidably remained. It seemed that the subclavian portion of the aneurysm was filled up with a solid clot, the radial pulse being absent to this day.

Dr. H. B. SANDS thought it might be a question whether the aneurysmal sac was completely obliterated. It was evidently firm, but pulsation was quite marked.

Dr. GERSTER perhaps might be allowed to correct himself in so far as he had said in his written history of the case that he believed a solid clot filled that portion of the aneurysm which belonged to the subclavian. The radial pulse had appeared only very lately.

Dr. L. A. STIMSON referred to a case, which he reported four years ago, in which he ligated the carotid and subclavian simultaneously for aneurysm of the innominate artery. There remained a distinct pulsation in the sac above the clavicle. The patient died twenty-one months subsequently of acute phthisis, and at the autopsy the aneurysmal sac was found completely filled by a firm clot except for a very narrow slit-shaped opening through which blood passed from the aorta to the branches of the thyroid axis. Of course, it could not be said positively that the condition at the autopsy was the same as that which existed at the time the patient was presented to the society, but up to the time of the patient's death there was pulsation in the sac, the same as when he was presented to the society. In his mind there was no question but that the pulsation was a communicated one, and in Dr. Gerster's case he should not regard the pulsation as proof positive that the sac was not occupied by a clot.

Osteoplastic Excision of the Elbow Joint.—Dr. STIMSON presented a patient upon whom he had performed excision of the elbow joint. He thought the case worthy of presentation because, first, the operation was a modification of one that had recently been introduced, and, second, because of the com-

plete restoration of the form, and the partial restoration of all the functions of the joint. The patient was a boy sixteen years of age, who, sixteen months before coming under observation, received a blow on the outer side of the left elbow, which was followed by swelling, heat, tenderness, and the formation of many sinuses in the arm and forearm. When Dr. Stimson first saw the patient the limb was swollen, the joint was painful, though capable of some motion, and there was lateral mobility with grating. The excision was performed on the 17th of May last. An incision according to Ollier's method was made, extending along the outer aspect of the lower end of the arm, and then diagonally across to the olecranon and along its outer edge. From this, at the lower end, a transverse incision was made across the ulna, the joint opened freely, and the olecranon divided obliquely backward at its thinnest part. The triceps and the adherent posterior part of the olecranon were then reflected to the inner side, and the joint was freely exposed, the inner condyle being denuded through a small incision over the epitrochlea, and then the humerus was divided by a transverse cut through the epicondyles. The surface of the olecranon was freely scraped, and it was necessary to remove almost the entire coronoid process. As this scraping had greatly enlarged the sigmoid cavity, he removed a segment of bone, one fourth of an inch in thickness, adjoining the incision through the olecranon, and thus shortened this cavity. Then, because of induration of the soft parts covering the front of the joint, he removed another slice one fourth of an inch in thickness from the humerus. The sinuses were then freely scraped, and the limb was dressed in the usual manner. The olecranon was reunited by silver sutures. The course of the case was uneventful. The wires were removed about two months after the operation. The patient now had very free motion in the joint, and good restoration of the form of the limb. Extension was particularly strong; flexion was weaker than extension. There remained an opening on the inner side of the arm, but it did not communicate with the bone. The patient could flex and extend the elbow actively. The bone was divided with an instrument brought to this country from England last spring, consisting of a combination of a forceps and a chisel-shaped saw, called an exsector. It was like an ordinary forceps with the claws at right angles to the handles, and on the side of the joint there was a small flat shell on a pivot, which held the saw and allowed it to be worked from side to side, and thus cut its way downward along the side of the claws. The instrument in his hands had proved very satisfactory.

Dr. GERSTER could not share with Dr. Stimson in his good opinion of the instrument mentioned. He had used it five or six times, and had seen it used by other surgeons, and he must say that it had two disadvantages: First, it was a complicated instrument, which easily got out of order, and was very difficult to clean; second, the leverage of the claws which took hold of the bone was disproportionately great, and he had seen the epiphysis of an infantile bone completely crushed by it.

Dr. STIMSON had not encountered any of the objections which Dr. Gerster had mentioned with reference to the exsector. He had, however, found it necessary to round the corners of the chisel in order to make it work more easily. The excessive amount of force which the instrument was capable of exerting Dr. Stimson thought was within the control of the surgeon who applied it.

Cases of Partial Resection of the Elbow and Shoulder for Tuberculosis, and of the Ankle for Traumatism, were presented by Dr. W. S. HALSTED.

CASE I.—Elbow.—A man, aged thirty-six, believed that a brother had died of consumption. His family history was otherwise good

About two years ago pain, spontaneous and insidious, developed in the right elbow, but until July, 1884, the patient's suffering had been inconsiderable. His sleep was little disturbed, and moderate movements of the affected joint did not cause pain. On his admission, July 22, 1884, there was consolidation at the apices of both lungs. The specific gravity of the urine was 1.028, and it contained oxalate of lime. There was a spindle-shaped enlargement of the right elbow joint, with fluctuating swellings to the outer side of and behind both condyles of the humerus. Flexion, possible only to less than a right angle, was painful. The inner swelling was incised and about one ounce of cheesy pus was removed. September 3d, the patient's elbow having for several weeks annoyed him greatly, injections of iodoform ointment were made through a fistulous tract into the joint, and contributed at first to his comfort. Anodynes, even in large doses, gave little relief. There was much redness about the joint, and the slightest motion caused great pain.

Ether having been given, Esmarch's bandage was applied, and as strict antiseptic precautions as practicable were observed. A longitudinal incision was made, eight inches in length, parallel to and just to the inner side of the inner border of the olecranon. Then a transverse incision was made, at right angles to the first one, outward to the plane of the radius, opening the joint and dividing the triceps muscle close to its insertion into the upper border of the olecranon process. A short longitudinal incision was then made at right angles to the second incision, and parallel to the outer border of the olecranon, to the neck of the radius. He preferred dividing the triceps to sawing through the olecranon, as proposed and practiced by Bruns, and practiced by Mosevig Moorhof and others, and by Dr. Stimson in the case just presented by him, because it was simpler in the first act, viz., opening the joint, and in the subsequent acts, should it prove necessary, as it almost invariably must, to remove the articular surface of the olecranon. The joint then being still more thoroughly exposed by liberating the sides of the olecranon from the triceps and anconeus attachments, all the articular surfaces were found to be more or less involved in the disease, which was distinctly tuberculous with, fortunately, sclerotic confines. The articular surfaces of the humerus, of the head of the radius, and of both sigmoid cavities were sawn off, also the upper surface of the olecranon. Thus a rectangular replaced the sigmoid cavity somewhat as figured in Leinhardt's "Operationslehre." The capsule and articular ligament were completely dissected out and the walls of the sinus scraped with a Volkmann's spoon. The end of the humerus was sewed with catgut into the step made in the olecranon, and the space necessarily left between the humerus and the radius was obliterated by turning into it the divided triceps and anconeus muscles, which were retained by several "*Einstülpungsnähte*." Other small dead spaces were obliterated by quilted sutures. Wound was closed by the furrier's suture, and three short drainage-tubes were introduced. The dressing was applied previous to the removal of Esmarch's elastic bandage, and the limb, flexed to about 45°, was preserved from constriction by the introduction, in the dressing, of narrow strips of wood to distribute the pressure made by the tightly applied bandage. The arm was, of course, maintained elevated for about thirty-six hours.

September 6th, the dressing was changed; the edges were perfectly united; there were no signs of inflammation.

15th.—Redressed; drains apparently almost absorbed. No pus. Rectangular splint applied.

26th.—A small subcutaneous abscess in the cubitus opened, apparently having no connection with the joint.

The patient, as presented, seemed to have a perfectly healed joint. There still remained in the cubitus the mouth of a subcutaneous fistula, about half an inch in length, which did not, apparently, lead toward bone. Although it was but six weeks since the operation, the patient could flex and extend the elbow moderately and without pain. Dr. Halsted advocated partial as opposed to so-called typical resections of the elbow joint for tuberculosis.

CASE II.—*Shoulder*.—I. H., male, aged fifteen years. No tuberculous heredity ascertained. All the members of his immediate family alive and healthy. About the middle of April, 1884, he wrenched his

left arm while lifting down a coal-scuttle. He felt pain immediately in the left shoulder joint, severe enough to prevent sleep for three nights. On the fourth day the pain had subsided, except on motion. A few days later he applied at the Roosevelt Hospital Out-Patient Department for relief. The muscles about the joint were then much atrophied. The head of the humerus on the affected side appeared smaller than on the sound side. The joint was not thickened at any part, but was fixed by muscular action. Passive motion and palpation of joint were painful. There were no points of special tenderness. A plaster-of-Paris splint was applied, and on August 20th, when the splint was removed, there had been no pain whatever since its application. There was a fluctuating tumor of about the size of a pigeon's egg at the back of the joint, under the deltoid muscle. The skin over it was normal. August 26th, about one drachm of flocculent pus was withdrawn from the abscess with a Pravaz's syringe, and iodoform ointment (iodoform, one part; almond oil, two parts) was injected into the abscess cavity. Examination of the pus, by Dr. R. J. Hall, revealed, from eight cover-glasses, five tubercle bacilli.

August 27th.—Patient was confident that he had been benefited by the iodoform injections, and unwillingly allowed a repetition of the aspiration and injection of the cavity, which had more than attained its former size.

September 14th.—Condition essentially unaltered.

16th.—Arthrotomy was performed by a posterior incision through the abscess, leading directly into the joint, which was distended with pus. The much-diseased head of the humerus was sawn off at the surgical neck; the glenoid cavity and capsule, also extensively involved in the tuberculous process, were scraped with a sharp spoon. The furrier's suture was used, and a short rubber drain was inserted at the lower angle of the wound.

30th, two weeks after the operation.—Original dressing removed. Wound healed, without pus, to the drainage-tube. Tube removed.

October 10th.—Second dressing.

November 1st.—Wound entirely healed. Free passive motion does not cause pain; active movements inconsiderable. Electricity applied to the deltoid.

On presenting the patient, whom he had not seen for one week, Dr. Halsted discovered a small fistulous tract at the lower angle of the wound.

The interesting features in the case were its traumatic origin, the immediate atrophy of the deltoid muscle, the failure of iodoform injections, the rapid healing of the wound, and the early partial restoration of function.

CASE III.—*Ankle*.—C. L., aged twenty-seven years, was admitted to Roosevelt Hospital October 17, 1883. Just before admission he had been thrown from a horse, and, as he fell on his feet, his right foot turned under him. The tibia and fibula protruded from an extensive wound on the outer side of the ankle, the foot being strongly supinated. Both malleoli were broken off and adherent to the dislocated foot. The patient was etherized, and the malleoli were removed, together with two inches or more of the lower ends of the splintered upper fragments of the tibia and fibula. The furrier's suture was used. A rubber drainage-tube was passed through the joint.

30th.—Wound dressed for the first time. Complete union along the lines of suture.

November 7th.—Second dressing; superficial ulcers where the drainage-tube had been.

December 14th.—Patient walks with crutches. On presentation, he walked easily with lateral brace. He could flex and extend the ankle quite as much as, if not more than, on the sound side, notwithstanding the shortened leg bones.

Corrosive-sublimate solution, 1 to 1,000, was used as the irrigating fluid, and iodoformized gauze as the dressing, in the three cases. The wounds healed in all primarily.

A Case of Impacted Extra-capsular Fracture of the Neck of the Thigh Bone.—Dr. J. C. HUTCHINSON read a paper with this title. [See page 604.]

Dr. FRANK H. HAMILTON was invited by the President to open the discussion on Dr. Hutchison's paper, and said: "I consider this paper of very great interest, not only in its simple narrative of the case, but in the valuable suggestions which it contains, and the more so because the author of the paper is a surgeon of distinction and experience, and therefore relates more intelligently his own personal experiences than they could have been related by a second person. For these reasons I hope the author will not withhold the name of the patient who received the injury.

"As to whether or not this was originally a case of fracture, I assume that it was one, for one or two other reasons than those stated by Dr. Hutchison. I am in the habit of assuming, when a man of the age and weight of the patient falls violently upon the trochanter major, that he has almost certainly received a fracture of the neck of the femur, probably extra-capsular. In deciding, in the case under observation, as to whether it was a fracture or not, this was a very important factor in the diagnosis. A second reason was, and of still greater importance, perhaps, that there was a manifest depression of the trochanter major. That the limb was a little shortened, one fourth of an inch, perhaps, subsequently one sixth of an inch, I might explain upon the supposition that this was normal. On the other hand, it might be that the shortening was actually greater than was represented by the measurement, because the injured limb was perhaps normally longer than the opposite limb. But, that there was shortening, all who saw the patient agreed.

"With regard to the muscular spasms, I do not say that they are absolutely diagnostic of an extra-capsular fracture of the femur, but, while they are often present in fractures of the shaft, they are almost universally present in fracture of the neck, especially of extra-capsular. I have explained this on the supposition that the muscles and the nerves in the vicinity of the fracture have been injured somewhat. The fullness in Scarpa's region, which occurred later, and which the doctor recognized, would at least lead us to suspect fracture.

"All the circumstances point so directly to extra-capsular fracture of the neck of the femur that I do not think we can entertain a doubt of its occurrence, but the greatest doubt is thrown upon the case by the remarkable result; that is, there is no eversion, no osteophytes are apparent, and the shortening is very slight."

Dr. HALSTED said that, when he examined the patient referred to by the author of the paper, he made out from five eighths to three fourths of an inch shortening; not only by measuring from the anterior-superior spine of the ilium to the external malleolus, but also along Bryant's line. It seemed to him to be sufficiently easy to tell whether the shortening was due to fracture of the neck or not by measuring from the top of the trochanter to the malleolus on both sides; but, if the shortening along Bryant's line corresponded to the difference in measurements made from the anterior-superior spines of the ilia to the malleoli, it was fair to suppose that fracture existed. He also noticed that the affected side was flattened extero-internally, and that there was an abnormal fullness behind the great trochanter, which strengthened his belief that a fracture existed.

Dr. STIMSON thought the two opposing facts mentioned by Dr. Hamilton did not seriously affect his diagnosis. There were many specimens showing that repair had taken place without the formation of osteophytes; and, as to eversion or limitation of inversion, that was a symptom dependent upon mechanical conditions which might or might not be present, for example, impaction with outward rotation of the shaft upon the neck. If the impaction took place, as in Dr. Hutchison's case, without such rotation, the range of eversion and inversion would not be

modified. The occasional great difficulty of reaching a diagnosis was admitted by all. In a case recently under his own care, resulting from a fall upon the trochanter while walking, the limb was slightly adducted and inverted, shortened half an inch, the trochanter being a third of an inch farther from the median line; there was no pain on pressure in front of, or behind, or upon the trochanter; there was inability to raise the head. Several surgeons saw the case, but declined to make a diagnosis. The shortening increased during the next week to one inch; then Buck's extension was applied, and in due time the patient left the hospital, walking without a limp, but with three quarters of an inch shortening.

In another case, sent to Bellevue from another hospital with the diagnosis of fracture of the neck of the femur, there was inability to walk or raise the heel from the bed, with sharp pain on pressure behind the trochanter; there was doubtful shortening of a quarter of an inch, but no fullness of Scarpa's space, and no pain when the limb was forcibly pressed against or pulled away from the body. The patient was left without any dressing, and in two weeks was able to walk easily, with only a slight limp. He was more than fifty years old.

Dr. C. K. BRIDGON had seen, some years ago, a case similar to the one related by the author of the paper. The patient was on a pleasure trip, more than a hundred miles distant from his home, when he was thrown violently, his hip coming in contact with the ground. He was transported on an extemporized stretcher to a baggage-car, and to his home, where Dr. Bridgon saw him in consultation with his family physician. The limb was disabled, he complained of a good deal of pain, could not raise his heel from the bed, there was slight eversion, the movement of inversion was limited, there was about half an inch shortening, gentle rotation of the thigh elicited no crepitus, and when the trochanter was grasped during such movement it was manifest that it described the arc of a lesser circle than on the opposite side. The diagnosis was, impacted fracture of the neck of the thigh bone. Rotation of the femur revealed one symptom which Dr. Bridgon had always regarded as characteristic of the lesion. In an *unimpacted* fracture, when the trochanter was grasped during rotation it would be felt that it was rotated through the axis of the shaft; when the fracture was *impacted*, the trochanter moved through an arc of a circle of which the head of the bone was the center, and the excursion made by the trochanter would depend upon the depth of the impaction.

Another symptom referred to in the case reported was fullness in the upper part of Scarpa's space. This could sometimes be felt in lean patients as a more or less bony prominence in the region of the neck, and, with the symptom of eversion, depended upon the manner of impaction, which was accounted for by anatomical considerations brought prominently before the profession by Professor H. J. Bigelow in his essay on "The Hip." From the examination of a number of museum specimens, he had concluded that the posterior portion of the neck was always driven in, and that the anterior portion was bent at an angle prominent in front. To ascertain the cause of this, sections of the sound bone were made, and it was found that near the junction of the neck with the head of the bone the anterior and posterior walls were of nearly equal thickness; but that, as the lower surface of the neck was approached, the anterior wall became of great thickness and strength, while the posterior remained thin, especially at its insertion beneath the posterior intertrochanteric ridge, where it was as thin as paper. Hence it was that the posterior portion of the neck was driven into the cancellated structure of the trochanter, causing the prominence in front, the slight external rotation, and the other signs already alluded to.

Dr. Bridgon stated that he had at the present time a patient

under his care in the Presbyterian Hospital, in whose case all these signs were made out by the most gentle manipulations, and without disturbing the relations of the parts, and he considered it as most important to avoid such handling as would be likely to break up any existing impaction.

Dr. A. C. Post said the case related by the author of the paper did not seem to accord with the opinion of Robert Smith, of Dublin, who stated that in extra-capsular fracture the initial force which occasioned the fracture always caused impaction; and, if more force than that which caused the impaction was applied, it split the bone through the trochanters and the impaction was relieved. The degree of violence in Dr. Hutchison's case seemed to have been sufficient to relieve impaction by splitting the bone at the junction of the trochanters with the shaft, and in this respect the case was exceptional, and the absence of splitting the shaft of the bone would explain the absence of osteophytes. Dr. Post further remarked that the ability to walk was not proof positive against fracture. Not long ago he had seen a case of intra-capsular fracture of the neck of the femur in which there was doubt with regard to the existence of fracture. The patient after a few days did walk, and there was subsequently displacement which left no doubt with regard to the existence of the fracture. Instances, he thought, were not very rare in which, the parts being held together firmly, the patient could walk, and we might assume that in such cases the parts might unite without further separation.

Dr. L. M. YALE referred to a marked case of this character which he had seen eighteen years ago, in which the patient fell, received his injury, walked a distance of one hundred feet, entered the wards of the hospital, and went to bed. It was a doubtful case of the kind, but, as the symptoms were those of probable fracture, he was sent to Charity Hospital, where he subsequently died of an intercurrent disease. The autopsy revealed impacted fracture of the neck of the femur.

Dr. STIMSON referred to a case occurring in a patient sixty-three years of age, who received an injury of the hip, walked down one staircase, along the hall, down the next staircase, and then was unable to walk, and was brought in that condition to the hospital. The patient died three weeks subsequently of erysipelas, and at the autopsy Dr. Stimson found a pure intra-capsular fracture of the neck of the femur.

Dr. SANDS said that Dr. Hutchison's case afforded a striking illustration of the difficulties experienced in determining the comparative length of the two limbs according to our customary mode of examination. It seemed that, of the several surgeons who examined the limb, no two reached the same conclusion, and that there was so great a difference of opinion as to make the shortening in one instance one sixth of an inch, and another from one half to three quarters of an inch, both surgeons presumably measuring between the same points. Of course, it would not be fair to assume that the length of the two limbs varied at the times they were measured, and the discrepancy arose from the difficulty in ascertaining what were called bony points. Such difficulty made untrustworthy the reports which were published of the results of treatment, for similar inaccuracies must occur in measuring the limbs after a fracture had consolidated. In many cases it might be easy to fix upon the bony points for measurement; but in persons who were fat it might be difficult or impossible to recognize them.

Dr. Sands had sometimes experienced the same difficulty in obtaining definite results with Bryant's test, and believed it to be untrustworthy when applied to those in whom adipose tissue was abundant. The difficulty was in recognizing the bony points—namely, the anterior-superior spinous process of the ilium and the tip of the great trochanter. Dr. Sands thought

that, in cases of fracture, the old-fashioned method of bringing the feet together—avoiding any obliquity of the pelvis—and then comparing the two internal malleoli would often give results quite as correct as those obtained by methods which we were accustomed to regard as more scientific. He believed that the practice of measuring between the iliac spines and the malleoli was far more prevalent in America than in Europe, where but little confidence was placed in it.

Dr. CHARLES MCBURNEY referred to the case of a man about forty years of age who three weeks ago came under his observation after the receipt of an injury of the left hip. The disability was great; but there was neither eversion nor inversion. As the patient lay upon a flat surface it was evident that there was apparently very great shortening of the limb on the injured side; that is, the sole of the foot on the injured side was drawn markedly above that on the uninjured side. On measuring the two limbs a curious discrepancy was detected. Measurement on the injured side from the anterior-superior spine of the ilium to the malleolus showed that there was one inch and a quarter *lengthening*. The absurdity of this was very apparent, and, on further inquiry and examination, it was found that the patient had had necrosis of the right tibia many years ago, tending to imperfect growth of that bone, and, on measurement, it was found that the entire discrepancy was in the length of the two tibiae. Dr. McBurney then measured along Bryant's line and found that the measurements were equal on both sides. The case proved to be one of contusion and not fracture.

Dr. STIMSON said that at one time he measured a large number of cadavers and afterward laid bare the bony points and repeated the measurements, and found considerable discrepancies between the results of these two measurements.

The PRESIDENT asked if the fact did not remain that, if unreliable within small ranges for diagnostic purposes, yet in actual practice the method of measuring from the anterior-superior spine of the ilium to the malleolus was sufficiently trustworthy for prognosis, as it was commonly accepted that, if there was three fourths of an inch or less of final shortening, the patient would get along without limping.

Dr. SANDS thought that the case reported by the author of the paper was one in point. The patient was examined by two competent surgeons. One determined the existence of one fourth of an inch of shortening, which afterward he reduced to one sixth of an inch; and the other found from one half to three fourths of an inch shortening. Now, if this had been a case in which the result of treatment was the point to be decided, two surgeons, equally competent, and employing the same method of examination, would have failed to reach the same conclusion.

The PRESIDENT said all would agree that it was sometimes very difficult to determine exactly the situation of the bony points; still he did not know of any readier way of making out the actual length of the limbs.

Dr. HALSTED thought the better way was to use Bryant's test.

NEW YORK CLINICAL SOCIETY.

Meeting of September 26, 1884.

Dr. L. B. BANGS in the Chair; Dr. L. ENMETT HOLT, Secretary *pro tem*.

Spasm of the Respiratory Muscles.—Dr. BEVERLEY ROBISON presented a patient, a man twenty-four years old, a German, by occupation a driver, who had been admitted into Charity Hospital on the 16th. The patient stated that he had always been perfectly healthy, with the exception of his present trouble and two similar attacks, one of which occurred at the age of seven and the other twelve months subsequently. His present attack

began about two weeks before his entrance into the hospital, without assignable cause. It consisted essentially in the fact that about every six or eight seconds he inflated his lungs to their fullest capacity by a somewhat spasmodic involuntary effort. Upon the slightest emotional excitement the frequency and spasmodic character of the successive inspirations were notably increased. During the time they lasted, the patient's countenance became rather dusky in hue, with slight pallor over the cheeks, the eyes staring and prominent, the trunk bent forward, and the hands supported by the knees, so as to give additional power to the inspiratory effort. After several of these exaggerated inspirations, he complained of vertigo and asked beseechingly for a drink of water. Swallowing water afforded him some relief for a few seconds when his attacks were the most severe. The attacks were always more intense toward nightfall, and, unless he took a full dose of some antispasmodic mixture, he could not sleep at all, owing to his spasmodic breathing. The remedy, among many that had been tried, which had afforded him the greatest temporary relief, was a mixture of equal parts of compound spirit of ether and compound spirit of lavender. The urine had been found normal.

The actual cautery had been applied to the back of the neck and he had been given large doses of chloral and atropine at different times, and continuously during several days, with only partial benefit. Singular to say, sulphate of atropine had been given him to the amount of one seventh of a grain (?) three times a day, according to the statement of the house physician, without appreciable physiological effects. This statement, it was needless to say, Dr. Robinson accepted very doubtingly—he believed that there was an error somewhere, or else that the drug employed was of very inferior quality.

Dr. Robinson regarded this case as very interesting, and in his experience it was a unique instance of spasm of the inspiratory muscles. The determining cause of the present attack was difficult to establish. What seemed most probable was that over-fatigue during the summer, added to an attack of suppressed perspiration (although unobserved), had brought it on. He thought it probable that the use of galvanism would prove of benefit.

[*Note by Dr. Robinson, October 28, 1884.*—The patient has much improved, but is not yet entirely relieved. His permanent improvement is possibly due to the use of moderate doses of iodide of potassium. Time also has been a considerable factor in bringing about the amelioration.]

Dr. ROBERT ABBE thought the disease was hysterical in character, being analogous to hiccough, and suggested the employment of will-power to control it, as he had seen this successful in intractable cases of the trouble referred to.

The case was considered a unique one by the members present, no one having seen anything just like it before.

A Peculiar Affection of the Finger Tips.—Dr. ABBE related a case of this sort, the patient being a man thirty-five years old, a driver. He had complained of pain in the tips of his fingers, and, beginning with the little finger, they had all successively become dark blue, as if going on to gangrene. This, however, did not ensue. There was pain in the palm, and the fingers themselves were hyperæsthetic. He had concluded that there must be some obstruction to the digital branches of the radial artery, and, on examination, this artery was found very small in the wrist, while the ulnar was enlarged. A history of syphilis was obtained, and a diagnosis of obliterating endarteritis was made. Iodide of potassium was given in full doses; in three days there was decided improvement, and in a week the blueness, which had existed for some weeks, was entirely gone. The finger tips had been distended, but there was no other œdema to be found.

Diabetes in Pregnancy.—Dr. GASPARD GRISWOLD referred to this subject, and related the case of a primipara whose urine, after albumin had existed in a moderate amount for a time and was gradually disappearing, was one day found with a specific gravity of 1.032, and, on testing for sugar, this was found to be present in considerable quantity. It persisted about a week and then disappeared spontaneously. There was no increase in the amount of urine, no thirst, or any other symptom of diabetes mellitus. In view of the statement sometimes made by writers on diabetes, that pregnancy never occurred during that disease, the case was of exceeding interest. He had found that Matthews Duncan had reported some similar cases—one in which a woman had sugar in the urine during her third, fourth, and fifth pregnancies, but no sugar at other times.

Dr. WALTER MENDELSON said that, as there were cases of albuminuria occurring in pregnancy in which no disease of the kidneys could be found, the cases being presumably of central nervous origin, the same explanation might hold good for cases of diabetes. Diabetes and Bright's disease were often associated in the same person, or were to be found in different members of the same family. The alternation of albumin and sugar in Dr. Griswold's case favored such a theory.

A Case of Face Presentation, in the mento-posterior position, was mentioned by Dr. J. H. EMERSON. Rotation was unusually rapid and easy, and the entire labor lasted less than an hour.

Miscellany.

THERAPEUTICAL NOTES.

Sulphate of Copper in Obstetric Practice.—The "Paris médical" publishes the following conclusions of M. Charpentier: (1) a solution of sulphate of copper, one to one hundred, is a most valuable antiseptic, especially in connection with midwifery; (2) the moderate price, absolute innocuousness, and convenient form of this substance are strong recommendations in its favor; (3) aside from its antiseptic properties, sulphate of copper is also a well-known astringent, so that it can be used as a substitute for persulphate of iron, over which it possesses the superior advantage of not retarding the healing of wounded surfaces. The solution may be used freely as an intra-uterine injection, without fear of unpleasant results; in fact, a rapid and steady recovery has followed its use in many cases of post-partum hyperpyrexia.

Iodoform in the Treatment of Tuberculosis.—Dr. R. S. Smith, in a letter to the "British Medical Journal," cites three cases in which he has made careful observations as to the influence of the iodoform treatment upon the *Bacillus tuberculosis*. In every case there were well-marked symptoms of phthisis—copious expectoration, rapid emaciation, and pyrexia, while the physical signs of consolidation were unmistakable. The sputa contained numerous bacilli. Iodoform was administered, in doses of one grain every four hours, and gradually carried up to two, three, and five grains, respectively. As a result of this treatment, the cough and expectoration ceased, there was a notable increase in body weight, and the physical signs were greatly improved. The bacilli, which had been noticed in such numbers at first, gradually disappeared from the sputa, until only a few remained. The writer acknowledges that these were selected cases, but he feels justified, from the evidence obtained, in assuming that iodoform really exercises a germicidal action upon the micro-organisms of tuberculosis.

Veratrine in the Treatment of Deafness of Labyrinthine Origin.—The following formula, suggested by Gruber, is published in the "Union médicale":

Veratrine.....	0.10	gramme;
Iodine	0.025	"
Iodide of potassium.....	1.00	"
Simple cerate	10.00	grammes.

In case of deafness due to exudation within the labyrinth, rub this ointment forcibly over the skin covering the mastoid process three times a day, for ten minutes at a time.

Clymer's Mixture for Asthma.—The same journal gives this anti-asthmatic remedy, suggested by Clymer:

Tincture of opium.....	4.00 grammes;
Sulphuric ether.....	8.00 "

Take fifty drops of this mixture every twenty minutes during the attack. Fifteen drops of the ethereal tincture of lobelia may be added to each dose.

An Ointment for Chromophytosis.—In the "Gazette hebdomadaire de médecine et de chirurgie" M. Vigier gives the following formula of an ointment for pityriasis versicolor:

Black soap.....	100.00 grammes;
Powdered pumice stone.....	50.00 "

Black soap, the writer explains, contains a considerable amount of potash; it forms with pumice a mixture having the consistence of simple ointment.

External Applications of Ether for Vomiting.—The "Paris médical" credits Dr. Galcedan with this suggestion. In a case of obstinate vomiting during pregnancy, after every remedy had been tried in vain, he applied some ether directly to the skin of the epigastrium. The effect was surprising; the patient inspired deeply several times, and ceased vomiting at once. Whatever may be the explanation of its action, this mode of treatment is certainly worth an extended trial.

The Treatment of Infectious Diseases with Intra-venous Injections of Iodine.—The "Wiener med. Wochenschrift" publishes a series of observations made by Dr. Van der Heyden, the results of which may be briefly stated as follows: In two cases of incipient cholera this method of treatment was quite successful; in more advanced cases, however, iodine injections produced no result. In three cases of lepra a marked improvement was observed. In typhoid fever a distinct diminution of the temperature followed the injections. The solution employed consisted of one part of iodine, two parts of iodide of sodium, and seven parts of water. Ten grammes was the amount ordinarily injected. Iodide of potassium was not used, because of the poisonous action which it seemed to exercise upon the heart muscle. In man, this intra-venous injection of iodine is easily effected by selecting the median vein. As a rule, no disturbance followed the injection, but in one case symptoms of collapse occurred.

The Action of Salicylate of Sodium on the Circulation.—Professor Maragliano publishes a series of experiments with this drug, the deductions from which are, briefly, as follows: Large doses of salicylate of sodium cause an increase of the ascending line of the pulse-curve, and an accentuation of the secondary rise of the descending line. The influence of the drug is not marked after three or four hours. The blood-pressure increases under the use of the salicylate. The conclusion is that the drug is absolutely devoid of the injurious effects upon the circulation which are generally ascribed to it.

Peritoneal Transfusion.—M. Hayem publishes, in the "Revue für Thierheilkunde," some valuable facts in reference to the injection of blood into the peritoneal cavity. The absorption, he states, is not dependent upon the amount of blood injected, neither is it influenced by the fact that the blood may have been obtained from an animal of a different species. The practical application of these facts is, that this method of transfusion offers a possible resource in cases of anæmia from severe hæmorrhage.

Hippurate of Lime.—Dr. Poulet publishes a long article on this substance in the "Gazette hebdomadaire de médecine et de chirurgie." His conclusions are that the drug seems to have a specific action in affections of the urinary organs, in diseases of the liver, in some skin affections dependent upon hepatic derangements, and, lastly, in certain digestive troubles. The formula which he suggests is as follows:

Hippuric acid.....	100.00 grammes;
Lime-water.....	q. s.;
Hot water.....	2 litres;
Sugar.....	2,400.00 grammes;
Tincture of lemon.....	15.00 "

The hippuric acid and lime-water are to be mixed with hot water until the reaction is no longer acid. Then add the rest of the water and the sugar. The dose is four drachms, to be taken two or three times a day.

Hydrochlorate of Apomorphine in Hystero-Epilepsy.—M. Laurentin, interne des hôpitaux, writing in "Lyon médical," states that he has employed subcutaneous injections of hydrochlorate of apomorphine in the treatment of this affection, with excellent results. He employed a solution consisting of fifteen centigrammes of the hydrochlorate and thirty grammes of distilled water. Two injections generally sufficed to cut short an attack. In closing his paper, the writer refers to successful cases reported by Wallender, Riegel, and Gower.

Different Uses of Cocaine.—Freud, in the same journal, summarizes the indications for this drug as follows: 1. As a stimulant in cases of bodily exhaustion. 2. In digestive troubles. 3. In the cachexia. 4. As a remedy in the treatment of the morphine and alcohol habits. 5. In asthma. 6. As an aphrodisiac. 7. To induce local anæsthesia.

A Topical Application for Warts.—M. Vigier, in the same journal, recommends the following formula:

Salicylic acid.....	1.00 grammes;
Alcoholic extract of <i>Cannabis indica</i>	0.50 "
Alcohol.....	1.00 "
Ether.....	2.50 grammes;
Flexible collodion.....	5.00 "

[Substantially, the foregoing is a well-known application for corns, and a very efficient one.]

Non-expert Testimony in Insanity Cases.—A ruling of the United States Supreme Court, the highest judicial authority in the country, on the question of the relative value of expert and non-expert testimony as to insanity, will be of interest to the profession. In a recent case, where the Connecticut Mutual Life Insurance Company was defending a suit on the ground that the policy-holder had killed himself when sane—a condition whereby the company was released from liability—the Court gave the following opinion: "Counsel for the plaintiff in error contends that witnesses who are not experts in medical science may not, under any circumstances, express their judgment as to the sane or insane state of a person's mind. This position, it must be conceded, finds support in some adjudicated cases, as well as in some elementary treatises on evidence. But, in our opinion, it can not be sustained consistently with the weight of authority, nor without closing an important avenue of truth in many if not in all cases, civil and criminal, which involve the question of insanity. Whether an individual is insane is not always best solved by abstruse metaphysical speculations expressed in the technical language of medical science. The common sense, and, we may add, the natural instincts of mankind, reject the supposition that only experts can approximate certainty upon such a subject.

"There are matters of which all men have more or less knowledge, according to their mental capacity and habits of observation—matters about which they may and do form opinions sufficiently satisfactory to constitute the basis of action. While the mere opinion of a non-professional witness, predicated upon facts detailed by others, is incompetent as evidence upon an issue of insanity, his judgment, based upon personal knowledge of the circumstances involved in such an inquiry, certainly is of value; because the natural and ordinary operations of the human intellect, and the appearance and conduct of insane persons, as contrasted with the appearance and conduct of persons of sound mind, are more or less understood and recognized by every one of ordinary intelligence who comes in contact with his species. The extent to which such opinions should influence or control the judgment of the Court or jury must depend upon the intelligence of the witness, as manifested by his examination, and upon his opportunities to ascertain all the circumstances that should properly affect any conclusion reached. It will also depend in part upon the degree of the mental unsoundness of the person whose condition is the subject of inquiry, for his derangement may be so total and palpable that but slight observation is necessary to enable persons of ordinary understanding to form a reasonably accurate judgment as to his sanity or insanity; in other cases the symptoms may be of such an occult character as to require the closest scrutiny and the highest skill to detect the existence of insanity."

Lectures and Addresses.

CONSERVATIVE PROGRESS.

THE PRESIDENT'S ANNUAL ADDRESS.

DELIVERED AT THE FIRST ANNUAL MEETING OF THE NEW YORK STATE MEDICAL ASSOCIATION,
NOVEMBER 18, 1884.

By HENRY D. DIDAMA, M. D.,
SYRACUSE.

THE advance of science is hindered not more by obstinacy than by fickleness. The skepticism which uses an honest crucible is a blessing; the skepticism which wields a club, and smashes old things indiscriminately *because* they are ancient, is a curse. Underneath its destructive malice is often a credulous and craven tenderness for anything which is new. One face of Janus was emblematic of Memory, and looked benignly upon the past, with its garnered treasures; the other represented Hope, and peered eagerly into the rich possibilities and promises of the future. These faces were not mutually inimical; they were complementary; they were unity in diversity. In medicine, bigotry and laziness sometimes call themselves conservative; opposed to these are discontent and love of novelty, which may assume the label progress; but genuine progress and enlightened conservatism work harmoniously together to perfect medical science; the one patiently tests all things; the other holds fast that which is good. In medicine much is worthy of conservation; not a little is still moot; research is very active and confident; vast fields await exploration. Your attention is invited to a few illustrations and suggestions.

In *pathology* the predisposing causes of disease are fairly well known by long and careful observation; but in the dazzling field of the microscope they are apt to be forgotten. Inheritance, acquired vices, insufficient, or improper, or excessive food and drink, vitiated air, deficient sunlight, exposures, indolence, overwork, worry—these are predisponents which act by so impairing the resisting power that attacking foes of feeble potency are able to gain an easy victory.

Many diseases, such as eruptive, contagious, and malarial fevers, pneumonia, consumption, erysipelas, septicæmia, pyæmia, and even suppuration, are now quite generally regarded as the work of micro-organisms—the *contagium vivum*.

The doctrine of germs is essentially modern, although Harvey is thought to have had glimpses of its truth more than two hundred years ago. But Harvey never regarded germs as living particles, capable of prolific multiplication; he considered the emanations from a certain disease able—by what he called a seminal influence—to propagate the same disease in a healthy person.

The witty Jonathan Swift, in the early part of the last century, described a microscopic specialist whose enthusiasm is hardly eclipsed by the zeal of any modern observer. He had discovered worms in the flesh of certain diseased animals, and he published an account of his observations. His paper attracted some attention and received favorable

comment. Inflated with flattery and vanity, the now famous discoverer continued to use his lens, and forthwith published the startling announcement that worms were the fountain and origin of all diseases.

In the present germ excitement—analogous to the gold fever of 1848 and the petroleum craze of later years—we are not to ignore other and well-established causes. We encourage the search for new *microzymes*, as we do prospecting for gold and oil; we watch intently each promising indication; but we prudently reserve our credence and wait for verifications of alleged discoveries, knowing that some observers have that keen vision pointed out in the couplet:

"Optics sharp it needs, I veen,
To see what is not to be seen."

We not only twine fadless chaplets for the modest brows of those who unearth a new *bacillus* whose pedigree can be established beyond question, but we bestow our admiration upon those ingenious philological microscopists who, if they can not diagnose hereditary diseases by the physiognomy of the blood corpuscle, are yet able to invent some magnificent name for the minutest pest which infests the human organism.

We urge that investigation can not be too extensive and thorough; but we counsel that there be no premature rushing into print with generalizations, lest the observations shall turn out illusory, lest alleged causes shall prove to be but unimportant coincidences.

The reward for patient work may be slow in coming, like the flour from the mills of the gods, but it will be of excellent quality at last.

If he is worthy of national gratitude who makes two blades of unnecessary grass grow where but one had a feeble struggle for existence before, how much more deserving of temporary immortality is he who establishes his claim to a new *cacozyme*, be it *bacillus*, or *micrococcus*, or *spirillum*, especially if he can tell us what to do with it!

The specific micro-organisms of tuberculosis and splenic fever and, perhaps, cholera have been differentiated; those of miasmatic diseases, seen as the *palmella* in Ohio by a genius of sharp optics, and as a *micrococcus* by Italian observers, remain to be verified. There should be little doubt of their existence, notwithstanding the incredulity recently expressed by an eminent writer who still pins his faith to the ancient notion that a poison is generated by decomposing vegetation. For, while a living and developing organism will account for all the facts of origin, incubation, and behavior of miasmatic fevers, a dead poison is quite unsatisfactory and insufficient.

But the germs which cause scarlatina, measles, pertussis, etc., have thus far eluded search. It is still an undecided question whether croupous pneumonitis is a germ fever with a local expression.

The suggestions of our eminent friend and associate who called attention to this point several years ago are entitled to, and are receiving, consideration throughout the world. Continued observations are still needed to confirm or overthrow the proposition.

In *therapeutics* conservative progress finds an ample

field. To prevent; to guide to a favorable termination, when prevention has been neglected; to alleviate, when recovery is impossible; to delay the inevitable escape of the soul from its weary prison—these are the important duties of the physician.

A thorough knowledge of the composition and structure of the body, and of the relation of parts, is indeed of great importance. The action of organs in health and their perverted action in disease rightly demand the most careful study.

The foes which boldly attack the citadel of life, and the occult influences which insidiously undermine and sap the vital forces, these may well engage our earnest attention. The fascinating analysis of our secretions and excretions, of our foods and medicines and poisons, deserves all the consideration which it receives.

The innumerable instruments of precision, which promise to substitute mathematical accuracy for vague guess, and which are too often used not to supplement but to supplant other and valuable methods of investigation, these, like the tribe of Abou Ben Adhem, will continue to increase till they become multitudinous—if not perplexing—like the grasshoppers of the West; these rightfully challenge recognition and study, while with unappeasable appetite they devour our substance if we attempt to add them all to our armamentarium.

But anatomy and histology, physiology, pathology and chemistry, ætiology, diagnosis, and prognosis; the possession of all the scopes, all the graphs, and all the meters, and the familiar and dexterous use of them—all these, interesting as they may be to the scientist, important and indispensable as they may be as preliminaries, foundations, and aids to medical skill, all these are practically worthless except as they contribute to the relief of human suffering.

"The real physician," says Broussais, "is the one who cures; the observation which does not teach the art of healing is not that of a physician, it is that of a naturalist."

And, paraphrasing Sacred Writ, it may be added: There remaineth therefore Pathology, Diagnosis, Therapeutics, these three; but the greatest of these is Therapeutics.

Therapeutics, then—which includes all means to prevent and manage disease—being the superstructure to which all medical ologies are but foundation-stones and adornments, the very fruitage of the tree of life, the sole beneficent application of all medical science, its importance to humanity, and therefore to the physician, can not be overestimated.

Efforts to elevate the standard of medical requirements are worthy of commendation. Owing to the fierce rivalry of schools and the facility with which incompetence secures its diploma, it has been deemed very important, by many reformers, to have the licensing power placed in the hands of an independent board of examiners.

Should such a board be constituted, it may properly require a thorough preliminary training; it may be so comprehensive in its demands and so vigorous in its examinations that no one guilty of ignorance regarding the fundamental branches of medical and other cognate sciences shall be able to gain admission to the ranks of a noble profession. But if, in these exalted demands and these exacting

examinations, therapeutics is ignored or belittled; if therapeutics is not elevated to the highest position and regarded as the one thing needful, the very vital principle without which everything else is but dead and useless science, and with which alone the physician does all his skillful deeds of benevolence; then the ordeal to which the candidate is subjected is delusive and beggarly. It may even deserve reprobation. The object of a board of examiners should be to protect the community from the ravages of additional incompetency. Its action must of necessity be prospective. It can not hope to uproot a professional ignorance which, associated with length of years and engaging manners, has become popular and almost sacred.

But it can determine the minimum amount of knowledge which must be possessed by every candidate who shall gain admission to the medical fraternity. If its examinations shall be comprehensive and searching, and at the same time not so narrow and technical as to regard an error in orthography less excusable than a gross blunder in medical practice, it may accomplish its good purpose.

But if it tithe, rigorously, the mint, anise, and cummin, and neglects the weightier matters of applied medical science; if it shows partiality, allowing Vitreus Cæruleus, who believes the radiance which filters through blue glass to be the only and omnipotent remedy for all diseases; and the gushing Aquarius, who dotes on and swears by magnetized spring-water as a panacea; and the innocent Credulus, who puts all his faith in faith alone; and the oily and plausible Sinbad, who pretends to be under the guidance of disembodied spirits—if the board allows these to shirk entirely the examination in therapeutics and materia medica to which plain, unpretending Medicus—who recognizes the importance of these sciences—is subjected, then when it puts these five on the same high level before the public, giving each the same indorsement and the same license, it inflicts a wrong on Medicus, places an unnecessary and useless burden on Cæruleus, Aquarius, Credulus, and Sinbad, and perpetrates a fraud on a confiding and misled community.

To serve the public wisely and well, the board should subject every applicant, whatever his callow crotchets, or prejudices, or intentions may be, to the same examination in every branch of medical science, as understood by the vast majority of the profession. Possessing the learning requisite to pass this examination, and endowed with his credentials, the tyro should be at liberty to adopt and practice any special delusion or idiosyncrasy which his fancy may indicate, or the credulity of the public make profitable. For, as he can never entirely divest himself of his useful knowledge, the community will have all the protection it is possible for an examining board to furnish.

Some of the general principles of therapeutics are worthy of the most careful preservation. Many of the measures employed in preventing and stamping out various so-called zymotic diseases are fairly successful; and constant research is adding largely to their numbers and potency. The importance of iodine and mercury in certain diseases; the palliative and curative effect of opium in a variety of complaints; the efficacy of Peruvian bark in miasmatic

affections; the desirability and possibility of preventing and subduing high temperatures in fevers and inflammations; the wonderful results secured by certain heart tonics; the neutralizing and eliminating measures which have shortened the term of rheumatism from six weeks to six days; the undiminished power for good of ferruginous preparations in suitable cases; the occasional utility and even saving power of the once abused and now as much maligned venesection—these are merely samples of therapeutic principles and practice whose truth is attested by countless critical, level-headed observers throughout the whole world.

New discoveries in ætiology, pathology, and *materia medica* will modify our views and constantly increase our ability to overcome disease. They will show us when to interfere actively, and when to watch and wait. And, while we hold fast to well-founded principles of treatment and to remedies whose adoption has been tried, we give a hearty welcome and testing to every new measure, to every new medicine, which has a satisfactory indorsement. We are hampered by no dogma; so that, while we are not seduced by utopian theories, while we make no experiments with obvious and gross delusions, and while we set our faces like flint against fraudulent pretenses and practices, we carefully consider every promising suggestion, by whomsoever made, and we gladly adopt every useful discovery and every tested new application of old principles and remedies.

Is not this platform broad enough to afford standing and working room for every one who seeks to know and practice truth?

It is fashionable in certain quarters to decry the medical schools of our country; to censure their practice of so oiling their portals that the grossest ignorance can find an easy and welcome admission; to inveigh against their methods of teaching; and to condemn the facile, if not farcical, examinations which permit incompetence to seize a title and go forth to prey upon the community.

Indiscriminate and unmixed reprobation is not only unjust; it defeats its purpose. For whatever may be the deficiencies of our great schools, however far they fall short of what they can and should be, they have excellences which should not be ignored. They have given to the profession men renowned throughout the world for their wisdom and skill. In their corps of teachers are many whose aptness and industry and ability are unsurpassed. They afford clinical opportunities so rich and varied as to leave nothing to be desired.

If their requirements for entrance and exit have been too low, is it not because the profession have not demanded higher? If the terms have been too short and the years required too few, and the methods unnatural and deficient, is it not because the profession have given little practical encouragement to the hearty, even if too speedily abandoned, attempts which some of the schools have made to secure needful reform?

Can it be doubted that the accomplished and devoted teachers in the schools are always ready and willing to respond to any earnest call of the profession for a higher standard? Shall this call be made? Will those who make the demand prove their sincerity by pledging their influ-

ence, their aid, and comfort to those schools which, at whatever labor and expense, shall eliminate the faults of the present system, and bring it into harmony with the teaching in all institutions of learning, and with the law of mental evolution and growth?

That brilliant results have been achieved under the prevailing system of medical teaching has not been, and can not be denied. Would they not have been still more brilliant and satisfactory under a better system?

The native Ceylonese, with instruments which would hardly be tolerated in an American blacksmith's shop, sits on the ground and patiently fabricates jewelry and filigree which are marvels of exquisite delicacy and beauty. Retaining his present artistic taste and skill, how much more and better work could he do with the perfected instruments of his civilized brother!

The superiority of the graded system of medical training is not universally acknowledged. At least one prominent teacher and one good medical journal openly profess not simply a contentment with the present unnatural system, but an admiration for it, and a desire to have it conserved. The attempts to reduce chaotic elements to order they denounce as impracticable, and they kindly predict and counsel their early abandonment.

Proposed reforms always provoke some opposition. The attempt to introduce into Mexican farming such modern implements as the steel plow, the cradle, the reaper, and thresher is earnestly combated by many of the native workers. They not only adhere to the sickle and to the old one-handed Palestine plow—an iron-shod stick which barely scratches the soil—and to the threshing-floor, where oxen and mules tread out the grain, but they insist that this clumsy system is the better. They bill their corn as our own farmers did fifty years ago. They use a hoe in the operation, but the hoe has no handle, and the native partly creeps and partly jumps, like a kangaroo, from hill to hill, as he goes through the field. Still he loves and reveres the old ancestral implement. He denounces the handle as a device to promote laziness. And he asserts that, with a primitive hoe in each hand, he can do more and superior work. It was only by compulsion that these earnest Mexican conservatives could be brought to use wheelbarrows on the public works. They preferred to carry their loads of stone and dirt on their backs and heads. And such was their devotion to their ancient method that at first they actually shouldered the wheelbarrow, dirt and all, and then vociferously condemned the new notion as a fraud and nuisance.

Honest differences of opinion should be treated with respect and tenderness. And, since these differences exist regarding medical education, it may not be unprofitable briefly to compare and contrast the antique system with the modern.

Most of you know, from personal experience, that in the large majority of medical schools in this country the student, at the very outset, is expected and required to hear lectures on all the branches taught—the most advanced as well as the elementary—every day. Although not usual, the occurrences to be described are by no means impossible.

An ingenuous youth, full of zeal, industrious, ambitious, but with scant knowledge of the elements of the most moderate education, is received without question at the grand old conservative college. He matriculates. He attends a lecture on anatomy—the first he ever heard of this important subject. He is delighted. He enters the laboratory and listens with pleasure and profit to the professor of chemistry. Truly, he says to himself, the ways of wisdom are ways of pleasantness, and all her paths are flowery walks of peace.

He hastens into the surgical department. The lecture is introductory. But in a few days, and while his knowledge of anatomy is still limited to an awful admiration for the suspended skeleton and for the tray of disarticulated bones on the table, the subject of the lecture is aneurysm.

The bright description, the lucid explanation, make the whole subject interesting and satisfactory. The eloquent professor describes the operation for ligating the radial artery in its lower third: "Hold the hand supine; make an incision two inches long on the radial side of the *flexor carpi radialis*. The integument and aponeurosis being laid open, the artery is at once brought into view."

This is all clear enough to you, learned Fellows, because you have received sufficient anatomical instruction. But the fresh pupil whom we are considering—one of us perhaps—whose hopes but a few days ago were radiant and towering, becomes perplexed and disheartened, if not disgusted, because he has no knowledge of what radial may mean, whether aponeurosis is an animal or vegetable, or whether the *flexor carpi radialis* is bone, nerve, or sinew, situated on the crown of the head or the sole of the foot.

After the wearisome—wearisome because incomprehensible—incomprehensible because the student has not been prepared to understand it—lecture on surgery is ended, the still plucky pupil ventures into the room where the professor of the art of medicine is showing how insufficiency of the tricuspid valve, by obstructing the onward flow of blood in the *vena cava*, may cause congestion of the portal system, and then gastric catarrh, hæmorrhage, and albuminuria. He does not doubt the truth of the demonstration. But it loses all its beauty and force because the poor fellow has not the slightest notion of what the tricuspid or any other valve may be, or where the *vena cava* or portal system is located.

In the obstetric department the same failure to comprehend the lecturer results from the same want of preparation. But the rules of the school require attendance on all the lectures. And so, hour after hour, every day is wasted, by an earnest and ambitious student, in listening to what he can not understand, and so neglecting the studies which are prerequisite.

The short winter course is passed, and the student emerges in the early spring, with a head full of jumbled and meaningless words, with muddled ideas of medicine, obstetrics, and surgery, and with insufficient knowledge of anatomy, physiology, and chemistry, because the time which should have been devoted to these fundamental studies has been frittered away in a dazed attendance on lectures he had never been prepared to understand. The next winter

he goes through exactly the same course, but he is now better able to comprehend the teaching.

In *building a dwelling house*, you prepare a plan—first consulting the good wife regarding the fitness of things—and then you go ahead decently and in order. You lay the foundations deep and broad and strong. You carry up the superstructure carefully and gradually, so that no cracks nor flaws shall afterward appear. You put on the roof, finish the rooms honestly, without veneer or graining, and wait a sufficient time before you move in with your family. You do not jumble all together, working an hour on the turret, another on the trench for the cellar-walls, and still another on window-sills and hard finish and joists and rafters.

If you were to *train for an athlete*, you would not unwisely overstrain your sinews the first day by doing work beyond your ability. You would begin with light weights and moderate walks, increasing the labor each day as the muscles became developed and strong.

In his attempt to *make an accomplished musician*, the wise teacher first trains the fingers and wrists of the pupil, and requires much practicing of the exercises and scales, till all the fundamentals are thoroughly mastered. He does not allow the aspiring youth to practice the rudiments in the forenoon, and then in the afternoon murder the symphonies of Beethoven, or attempt to render the brilliant lunacies of Wagner, at the very outset of his career.

If it should be proposed to *evolve a mathematician* out of raw material, we would not ask the candidate the first day to solve the problem of the hare and hounds, nor to listen to a demonstration of the twelfth proposition of Euclid. We would begin with the simplest examples in addition and subtraction, and then advance through the higher and still higher departments, till at length, like Le Verrier, the fully developed candidate could discover and locate a planet by pure mathematical calculation.

In *training a child to be a linguist*, we begin with the simplest form of speech and lead him on, by precept and example, till he can speak with the tongues of men and of angels, and have charity besides. It would be unnatural, and therefore unwise, to allow him to waste time at the start in listening to the sounding brass of Cicero's orations, or the tinkling cymbals of Xenophon's fables.

If in every other department of human industry the natural development plan is pursued without opposition or question, why should medical education be the marked exception? Why, if we wish, as we ought, to *utilize to the utmost the time and talents of a medical student*, should we not take him step by step—for that is what the graded course means—through anatomy and physiology, histology and chemistry up to surgery, and practice and obstetrics? Why should we have him fritter away the scant but precious hours of his first course of lectures in listening to what he can not by any possibility fully comprehend? Would not this be doing what ought not to be done, and leaving undone what ought to be done?

The natural system of medical education is no longer a beautiful and dreamy speculation. It has been fairly tested, and it has been found efficient. Those who know it best

give it the heartiest approval. The requirements for matriculation are, or should be, more and more exacting every year. The written and oral examinations are frequent and thorough. The yearly and final ordeals are very trying and severe; but the students who have brains, application, and faithfulness, always come through triumphantly. Even those whose natural capacity is not the greatest succeed remarkably. Under a natural system their mental growth is rapid and astonishing. At the last they seldom fail, because their time has been husbanded and properly employed, because their studies have been interesting and delightful, inasmuch as they have been thoroughly comprehended and mastered, every step of the way.

Here are two pictures. Do they not represent the prominent differences in requirements and results between the ancient, but still prevailing system, and the modern one?

In one case no preliminary examination; only two short courses of lectures required, the second identical with the first; the novice required to attend lectures on every subject every day, neglecting preliminary work because the time which might have been devoted to it has been worse than wasted in hearing learned talk which he was not prepared to understand; valuable clinical and laboratory opportunities; no examinations to advance to higher grades, for there are no grades; a final examination which is so superficial in many instances as to be little better than a farce, and whose meshes are large enough to let mediocrity and inferiority, as well as the superiority which is always present, pass through with the greatest ease.

In the other case preliminary examinations which require a certain, even if insufficient, preparation; three years of training at the college, the novice beginning at the beginning; all his time employed in hearing and doing what he can and should understand; his capability and progress tested by frequent oral and written examinations; his advance from grade to grade checked if his fitness is not established; valuable clinical and laboratory opportunities; searching yearly examinations; and a final examination, which, although of great severity, does not, except in rare instances, result in rejection, because the student has been educated in a way which accords with nature and does not violate it.

Of these two systems, judge ye which is the better.

And yet the difference between the old system and the new is greatly one of arrangement. A change from one to the other can be effected with as little commotion as was noticed when twenty discordant and puzzling computations were consolidated into the present admirable system of standard time.

No more teachers would be required; no better lectures could be delivered, or would be needed. The labors of the professors would be considerably increased because the total length of the lecture season would be more than doubled, but they would hardly be conscious that a radical change, amounting to a revolution, had taken place. But the students, who are to be the physicians of the future, and the confiding patients of these physicians, would derive incalculable benefit.

Would not the adoption, by all the schools of this country, certainly by those of this State, and especially by the three prominent ones in this medical metropolis, of the natural system, with the honest and vigorous enforcements of its entire demands, secure a practical elevation of the medical standard, so much yearned for, deserve the support of the profession, and restore a confidence which has been seriously impaired? Would not this adoption protect the community to the greatest extent possible from incompetence, and render unnecessary, so far as legitimate medicine is concerned—the only medicine about which we have any solicitude—the proposed State board of incongruous medical examiners?

And now, Fellows of the Association—good fellows and patient, one and all—I thank you for the very great, and, of course, unsought honor—for it would not be an honor if I had sought it—you have conferred in choosing me to be your first presiding officer. I confidently count on your kindly forbearance and your generous assistance. I congratulate you that our first meeting begins so auspiciously; that the promised material for our coming three days' scientific festival has never been surpassed in richness or variety. I cordially invite each and every one to contribute to the success of the feast.

Original Communications.

HAY FEVER AND ITS SUCCESSFUL TREATMENT.*

BY CHARLES E. SAJOUS, M.D.,
LECTURER ON LARYNGOLOGY AND RHINOLOGY IN JEFFERSON MEDICAL
COLLEGE, PHILADELPHIA.

At a meeting of the Philadelphia Laryngological Society, held on the 23d of last November, I read a paper entitled "Notes on Hay Fever," which was published on the 22d of the following month, and reported a series of cases in which the accesses were prevented by what might be termed organic alteration of the surface of the nasal mucous membrane.

In the contribution herewith presented I am obliged to quote largely from that paper. I must state, however, that a number of cases have been added to the list, and that close observation has furnished me valuable information which has led me to doubt some conclusions arrived at at the time, while strengthening others.

In the spring of 1881, while investigating, at the Jefferson College Hospital, the merits of glacial acetic acid in the treatment of intra-nasal hypertrophies, I came across two patients who stated, in the course of their general history, that they were subject to hay fever. Both had middle turbinate hypertrophies, complicated in one case with a posterior growth, causing complete stenosis of the left naris. Glacial acetic acid was used to destroy the anterior growths, while the posterior was extirpated with Jarvis's snare. Bearing the hay-fever history in mind, I applied the acid over a

* Read before the American Laryngological Association, May 14, 1884.

much greater surface than was necessary for the destruction of the hypertrophies, hoping by this means to diminish the sensitiveness of the mucous membrane, primarily affected in the course of the hay fever, and if not prevent, at least diminish, the intensity of the accesses. When the time came for the hay fever to manifest itself I watched the cases closely. The symptoms did not recur.

In studying the *modus operandi* of the treatment in bringing about such a result, we must adopt the generally accepted theory that hay fever is due to an idiosyncrasy on the part of certain individuals to become affected by certain emanations. The experiments of Blackley show that the pollen of the majority of plants is the agent that produces the impression on a system sensitive to its action, and that, this pollen being disseminated throughout the atmosphere at certain fixed seasons, the symptoms present themselves only at fixed seasons.

That this is the true theory seems to me beyond a doubt, for without it we can not explain the regular recurrence, and why this recurrence should take place just at one time and not at another. Still there are cases in which dust, for instance, will cause an access, the symptoms being those of a severe coryza. But, if we bear in mind that the nasal mucous membrane of persons affected with the idiosyncrasy of hay fever is in a state of chronic hyperæsthesia, we can easily understand why an irritant will cause in those persons much more violent symptoms than in others in whom the idiosyncrasy does not exist. Every nose is more or less irritated by dust, and the degree of irritation is in proportion to the degree of sensitiveness. Others are influenced by the emanations of certain drugs; in these the idiosyncrasy is not limited to pollen, but includes those substances that will cause an access.

Some authors have of late advanced the idea that malformation of the nasal cavity, either congenital or through hypertrophic changes, might be the cause of the manifestation, either by reflex action or by interference with nasal respiration. That such malformations have great influence as to the intensity of the manifestation is, I think, very certain, but it seems evident to my mind that they do not act as a cause. If such malformation were necessary, how could we explain the occurrence of an access in those cases in which no such malformation exists?

Mrs. A., aged thirty-eight, had been subject to hay fever for eleven years. Her attacks lasted four weeks, and were accompanied with severe asthma. She tried all nostrums recommended to her, including patent medicines; nothing seemed to help her, excepting a trip either to the sea-shore or to some elevated region, when the access would cease at once. A trip interfering greatly with her household duties, she was anxious to be delivered of her yearly punishment. She placed herself under my care three weeks prior to her last access, with premonitory symptoms, violent sneezing on rising already very evident. Careful examination revealed an unusually spacious and healthy nasal cavity, verifying her statement that, with the exception of her hay fever and a slight coryza when she inhaled dust, she never had trouble with her nose, and could breathe freely through it. Applications of the galvanic cauterium were immediately begun, and repeated until the membrane covering the middle and inferior turbinated bones and the lower half of the sep-

tum had been well singed. The premonitory sneezing stopped at once.

This case, with two others in which no malformation or intra-nasal hypertrophy sufficient to cause any degree of pressure existed, shows clearly that pressure can not be adduced as a cause. As to interference with nasal respiration in the course of an access through partial or complete stenosis induced by the engorgement of the nasal corpora cavernosa, I can not see clearly how it can be considered as a cause, since the engorgement is secondary to the cause of the exacerbation.

I am of the opinion that a permanent hyperæsthesia of the nasal mucous membrane exists in persons in whom an idiosyncrasy to become affected by the pollen of flowers or certain irritating substances is present, and that, as was the case with the two patients treated three years ago, the destructive agent employed had induced an organic transformation on the surface of that membrane which destroyed that morbid irritability attended the nervous filaments distributed over it. In other words, they had so altered those parts primarily affected in the course of an attack that they were no longer sensitive to the foreign elements acting as an exciting cause.

As an illustrative case, I will cite that of a young lady whose accesses had appeared regularly for several years. The applications not only prevented the symptoms, but made her nasal membrane absolutely invulnerable to the effects of pollen and other irritants. As a test, she exposed herself as much as possible to the emanations of the plants which she knew to be the most liable to occasion a manifestation of her idiosyncrasy, and went even so far as to place bouquets in her bedroom, and to approach a field of clover, her most dangerous enemy.

Had the idiosyncrasy itself yielded to the treatment, or had it ceased to exist in the patient? Neither can be the case, for one of the symptoms, palpebral pruritus, occurred, showing that the idiosyncrasy still existed in the patient, but that the organic alteration in the nasal membrane had annulled its liability to infection, thus preventing all symptoms secondary to its abnormal irritability, but not that manifested in the palpebral conjunctiva, which was irritable *per se*, and had not, of course, been cauterized.

The applications were made principally over the surfaces of the lower and middle turbinated bones and the portion of the septum corresponding with those surfaces.

The mucous membrane covering these parts is supplied by the inferior nasal branches of the large palatine nerve, which is derived from the sphenopalatine ganglion. They enter the nasal cavity through foramina in the palate bone. Now, the sphenopalatine ganglion possesses, besides its motor and sensory roots, a sympathetic root which is derived from the carotid plexus through the Vidian, and forms the connecting link between the nasal membrane and the sympathetic system, establishing an intimate and direct inter-communication between that membrane and the sympathetic system, through the largest of the cranial ganglia.

Organic alteration of the area over which its branches are distributed, preventing a manifestation of the idiosyncrasy, and the near proximity of this ganglion, explain, it

seems to me, that it is through it that the impression which gives rise to what remote symptoms the patient may be liable to is transmitted to the general system. Thus we can trace a direct connection with the lungs, in relation with the frequently present symptom, reflex asthma; the superior cervical ganglion, from which the branch forming the carotid plexus is derived, is connected with the inferior ganglion of the trunk of the pneumogastric, which involves the whole of the fibers of that nerve, with the exception of one, while in the thorax the posterior pulmonary plexus is not only formed by branches of the sympathetic, but also by some from the pneumogastric, and the two thus combined follow the ramifications of the air-tubes. Here their course is dotted with small ganglia, and their filaments become lost in the minute unstriped muscles of the bronchial tubes which were shown by Salter to cause, when thrown into a state of activity, the mechanical contraction which gives rise to the asthma.

In passing, let me state that this author says that "asthma consists of a perverted sensibility of the nervous system in its transmitting on to the muscle as a stimulus to contraction that of which it should take no cognizance. . . . The vice consists not in the production of any special irritant, but in the irritability of the part irritated."

To asthma as a symptom of hay fever this theory can be well adapted. The affection first manifesting itself in the nasal mucous membrane, this, then, is the seat of that morbid irritability; from it is transmitted through the nervous system that which causes spastic contraction of the fiber-cells of the organic muscles in the bronchial tubes.

I alluded to the influence exerted by intra-nasal malformations, either congenital or due to hypertrophic changes, on the intensity of the manifestation. A number of cases have been reported in which the accesses were avoided by the removal of hypertrophies. I am inclined to believe that the destruction of these hypertrophies was but of secondary importance in the effect produced, and that the organic changes occasioned by the cautery in the mucous membrane altered its hyperæsthesia. I am far, however, from considering malformations as innocuous in the history of the affection. I am so penetrated with the idea of their importance that I invariably resort to surgical procedure if they induce pressure or prevent the thorough application of the galvano-cautery. We are all familiar with the reflex asthma of some cases of nasal polypi, caused, in my opinion, by pressure on the branches of the sphenopalatine ganglion, and transmitted to the lungs as described a moment ago. Bearing their occurrence in mind, we certainly can accept the fact that asthma can be caused by the pressure of an engorged hypertrophied mucous membrane in the course of the violent inflammation engendered by the irritant to which the patient is sensitive. The asthma may even be kept up long after the other symptoms have ceased, hypertrophic changes in the membrane and the bones having been sufficiently developed to induce constant pressure, as in the following case:

Dr. H., a prominent Catholic clergyman of Philadelphia, had had regular annual attacks of hay fever for about twenty years. His last had been unusually severe,

and was followed by asthma, which, instead of disappearing as formerly, remained, manifesting itself especially after he had been in the recumbent position for some time. Examination revealed almost complete stenosis of the left naris, due to pressure of the septum. The latter, however, was not deviated sufficiently to account for the narrowness of the chamber, but was found, by means of the septometer, to be over a quarter of an inch thick at the point of closest contact. What hypertrophied tissue could be reached was cauterized without, however, inducing much change. I then concluded to diminish the abnormal thickness of the septum, which was done by passing the bur of the surgical engine under the mucous membrane and holding it in contact with the vomer until about half of its thickness had been removed. A free passage for the air was established and the contact relieved. The asthma disappeared.

In another case a prominence in the middle of the septum was reduced by the file, this also being passed under the mucous membrane.

If there is a deviation of the septum, and this interferes with the proper application of the cautery, I as much as possible correct the deformity. Hypertrophies are destroyed with the snare or cautery, according to their location.

In my early cases I used glacial acetic acid, but I had to abandon its use because, in order to obtain satisfactory results, it had to be applied repeatedly over an extensive surface, giving rise to much pain. The galvanic cautery serves me better, requiring but few applications, and being painless if properly used. I apply the cautery-knife with its flat side on the surface of the membrane, repeating that procedure in as many sittings until the whole surface extending over (and as much as possible under) the middle and inferior turbinated bones is well singed.

It would seem that such a radical alteration of the nasal membrane would occasion either a loss of, or at least impair, the sense of smell. This is not the case if the applications are properly made. The "olfactory membrane," which in man is yellow, covers the upper part of the septum, the superior turbinated bone, and the upper part of the middle turbinated; it is consequently but slightly involved in the treatment. On the contrary, olfaction is often improved by it, the reduction of the tumefaction facilitating the passage of air, and consequently that of the odoriferous particles. I have never had the least bad result, the treatment being successful and permanent in every case when thoroughly applied.

As a *résumé*, I would submit the following:

That hay fever is an idiosyncrasy existing in certain individuals, to become influenced by certain emanations or irritating substances.

That the idiosyncrasy is accompanied by a chronic hyperæsthesia of that part of the nasal mucous membrane covering the inferior and middle turbinated bones, the middle meatus, the floor of the nose, and that part of the septum below the limit of the olfactory membrane.

That organic alteration of those parts annuls that hyperæsthesia, preventing at the same time what symptoms the patient may be liable to in the course of an access.

That any destructive agent will induce that organic alteration, but that the galvanic cautery is by far the best, being painless, effective, and devoid of all danger when used in practiced hands.

That, in order to obtain a satisfactory result, a sufficient number of applications must be made, covering the entire extent of the over-sensitive surface, without which the result will be doubtful.

Now, gentlemen, permit me to state, in conclusion, that prior to last Saturday, and *after this paper had been written*, I knew nothing of Dr. Roe's (of Rochester) theory of hay fever, his method of treatment, and his results. The contribution I have just had the honor of presenting to you embodies precisely those views, and the results shown indicate evidently that the theory is the true one. Since I can not come in first, I am happy to come in a good second, for I feel that I have done something to strengthen in your minds the assertions set forth in Dr. Roe's excellent papers on the subject. Nothing can be stronger than unbiased, independent research and subsequent arrival at identical results. We were separated by hundreds of miles, unaware of each other's labors, and still the same point was attained, which gives us good reason to think that another affliction of humanity can be mastered. I feel happy at this coincidence, not only because I have given strength to Dr. Roe's views, but also because I feel very much stronger in mine; but I wish to call your attention to the fact that his first success was attained in 1879, while mine was only two years later. To Dr. Roe, then, belongs the honor of having first brought before the profession means for the radical cure of one of the most intractable diseases with which it has had to contend, and to the American Laryngological Association the merit of having been the *stimulus* that brought forth a paper which will only be what the first stone is to a monument.

DISCUSSION.

Dr. SHURLEY said: I have seen three cases, one of which was of the neuralgic form, and the other two true hay fever. In operating I had not followed exactly the practice laid down in Dr. Sajous's paper. Instead of singeing over the entire surface, I have simply cut just through the membrane, not very deeply, and finished up one side at a sitting. Previous to operating I have been in the habit of ascertaining with a little probe the limits of the hyperaesthesia. In one case I found it confined to the middle turbinate bone, and operated upon that alone. The last case operated upon I have not heard from since the operation. In another case the cure has remained perfect for eighteen months—up to the present time. The patient had suffered for years, and in other respects was healthy; there was no hereditary history of the disease.

Dr. ROE said: I am glad to find that the author's experience so fully coincides with my own. With regard to the permanent effect of the operation, in only one or two cases have I found any return of the trouble whatever. One patient was operated upon in 1879, with no return of the affection. One patient who underwent treatment about two years ago had a slight irritation in one nostril the following summer, but it was found to be due to lack of thoroughness of treatment, and I believe that where there is any return of the difficulty it will be found to be due to the fact that the entire sensitive area has not been treated. A means of determining whether or not

treatment has been effectual is the use of the probe, touching the surface with it—if any sensitive point remains, the patient will manifest it at once when touched. I have many times brought on marked attacks at once by touching the sensitive spots. In one case the attacks were brought on by touching the superior portion of the nasal septum on one side. The patient did not continue treatment until I felt satisfied that he was cured, and during the summer he had another attack. In the autumn and winter it was found that a sensitive point yet remained untouched.

With regard to the way in which asthma is brought about, I do not quite agree with the author that there is spasm of the bronchial tubes. I think it due to congestion of the mucous membrane. Irritation of the nerve produces engorgement of the pulmonary vessels, and asthma is thus produced. This theory is verified by the clinical features of the case. After an attack of asthma there is always a good deal of expectoration, and, as soon as the expectoration becomes free and the tubes are clear, the asthma subsides. If there was simple spasm of the bronchial tubes, we should not expect this free exudation.

As to the different exciting causes, some are due to engorgement and hypertrophy of the nasal membrane. In such cases we have to destroy the hypertrophic tissue, and if there are any exostoses of the turbinated bones, or of the septum, it is important to remove them in order that no occlusion may take place by swelling of the mucous membrane. It does not follow, however, that all persons with nasal stenosis have hay asthma. It would seem that there must be, back of this exciting cause, an idiosyncrasy affecting the terminal fibers of the nerve in the nose. It is sufficient simply to remove the irritability, and destroy the deeper plexus of vessels, so that no engorgement can take place, and, when we are sure that we have removed all irritability, we can also be sure that we have cured our patient. If any irritable area remains, we may be sure that our work has been incomplete.

Dr. MACKENZIE said: Reference has been made in the discussion to the well-known but imperfectly understood personal susceptibility or "idiosyncrasy"—a term which has been used to cover our ignorance concerning the pathology of the disease. I propose to substitute for the meaningless term idiosyncrasy that of abnormal excitability of the vaso-motor nerve-centers. While it is undoubtedly true that certain conditions of the nasal passages are necessary to the production of a paroxysm, I think it equally certain that in a number of cases such conditions are brought about by abnormal functional activity of the nerve-centers, and that, in our zeal as specialists, the importance of the latter as an aetiological factor should not be lost sight of. I think, therefore, the theory of organic change in the terminal fibers, as advanced by Dr. Roe, and that of nasal obstruction, as advocated by Dr. Allen, inadequate to account for the phenomena of the disease in question. The essential, distinguishing feature of so-called "hay fever" resides in an exalted condition of erethism of the nasal erectile tissue, and especially that portion occupying the posterior end of the inferior turbinate bone and the septum immediately opposite—an area which I believe to be especially concerned in the production of the nasal reflexes. This area corresponds, as I have shown, and as had been subsequently pointed out by M. Longet to the distribution of the two sphenopalatine nerves, as distinguished from the nasal branch of the ophthalmic, which latter supplies the anterior portions of the nasal fossæ. The former nerves are derived through the ganglion, and probably, therefore, contain the vaso-motor filaments that govern the erection of the turbinated tissue. Hence the discovery of the sensitive area in the posterior part of the nasal fossa becomes the key to the

mechanism of the paroxysm, and brings us nearer the solution of its pathology.

This exaggerated irritability of the cavernous tissue may be directly due to the constant presence of congestion or other pathological conditions of that structure, the result of direct (or reflex) stimulation from *ab extra* influences, plus an over-sensitive state of the nerve-centers begotten of their constant excitation by the irritation in the nose; or it may be brought about, in the first instance, by an exalted state of the central nervous system, leading eventually to disordered functional activity of the vaso-motor centers; or, finally, an over-sensitive condition of the latter may be conditioned by other pathological states of the system as a whole, or as the result of reflected irritation from its individual parts. As an example of the latter, I may refer to a case where the paroxysms were probably occasioned by disease of the ovaries. There is, practically, an infinity of causes, external and internal, which may precipitate the nasal orgasm, such as various forms of matter in the atmosphere (odoriferous particles of certain plants, germs, fruits, forms of animal life, etc.), or the same result may be brought about by causes commonly productive of erection of the nasal tissue, such as varying meteorological conditions, etc. I have provoked the paroxysm by irritation of the sensitive area with the probe. Whatever be the original cause of such special tendency to erection and evolution of reflex phenomena, the essential part of the mechanism of the paroxysm is the congestion and consequent orgasm of the nasal erectile area. In accordance with these views, the treatment should consist in the careful search for, and appropriate treatment of, any source of central or reflected irritation, the exclusion of local irritants, and the topical treatment of existing nasal disease. The latter will generally consist in *the destruction of that portion of the erectile area supplied by the sphenopalatine nerves.* By this latter procedure the essential part of the mechanism by which the paroxysms are produced is abolished, and the machinery which puts them in action stops.

I agree with Dr. Roe that the best method for destroying cavernous tissue consists in the skillful use of the galvanic cautery.

Dr. BEVERLEY ROBINSON said: I have had but comparatively little experience in the treatment of hay asthma, but I would ask the experience of those present in the use of carbolic acid. Last summer a lady came to me who said she had suffered from hay asthma for some years, and was then in the beginning of an attack. Happening to have some pure carbolic acid at hand, I covered a probe with it and passed it through the nose on both sides of the septum. Within a day or two she returned and said she had been greatly relieved. I made three or four more applications, and she has remained practically cured. Since that time I have had occasion several times to apply carbolic acid in the treatment of nasal catarrh, with excellent effects.

Dr. ROE said: I can not agree with Dr. Mackenzie regarding the pollen theory. I believe that hay fever is due to pollen. If they were not, why should the attack occur usually at a certain period of the year, the patient perhaps being able to tell the day and hour when it will come on, corresponding to the season when certain grasses and plants throw off their pollen. Many patients can tell the particular weed which affects them (commonly the ragweed), and by avoiding this can avoid the attack. I am therefore convinced that the pollen theory is correct.

Dr. JOHNSTON said: In my own case I never suffer from catarrhal troubles except in August, and usually on the 28th of that month I expect an attack of hay fever. I am less likely to suffer if I avoid the fields, the railroad cars, and dusty places. Last summer I went to Washington and had a severe attack; but

on reaching the mountains, three hundred feet above the sea, the attack at once disappeared; when I returned to Washington, the attack was renewed. I obtained relief by inhaling morphine, chloroform, or eucalyptus.

Dr. MACKENZIE, having understood Dr. Roe to say that all cases were due to the pollen, said that, while it was undoubtedly true that most attacks came on during certain months of the year, and many patients could predict with absolute certainty the day and even the hour of the attack, this was not universally the case by any means. There were patients who had hay fever in the winter, the attacks being just as severe as in the summer, and apparently due to a change in meteorological conditions. There were, in fact, innumerable different things which would precipitate an attack. He knew a patient who could bring on a paroxysm by stepping on the cold floor after rising from bed in the winter.

Dr. ROE remarked that persons might be exposed to pollen even during the winter.

The PRESIDENT said: I have seen at the dispensary a great many cases of this affection, which I think might better be called vaso-motor rhinitis, and in every case I believe three elements exist to bring about an attack—namely, a nervous or neurotic element, which has already been shown so conclusively to exist; a structural change in the nasal cavities; and a sensitiveness to the influence of some extraneous agent, as ragweed, etc. Now, remove any one of these three elements, and we prevent the attacks. This may be done by different means. For instance, I have a patient who went systematically to work to overcome the diathesis by hygienic means, and he completely cured his case by thus removing the neurotic tendencies. If a patient is sensitive only to the ragweed pollen, by avoiding that he will avoid the paroxysms. If the other element, the peculiar condition of the nasal membrane, is removed, this also will prevent the occurrence of the attacks.

Dr. SAJOURS, in closing the discussion, said: In speaking of the nasal condition, I did not mean to overlook the reflex center. It amounts to the same thing. The nose is the most exposed surface to irritation; but let the irritation exist in the knee, vagina, or rectum, the phenomena being reflected to the nose, and we have the paroxysm. In some persons, however, the nasal mucous membrane may not be so sensitive as some other portion of the body, as the vagina or rectum, and in such cases the point of origin of the reflex irritation will be in the more sensitive localities. I do not advocate the theory that pollen alone is the exciting cause, but rather a hyperæsthesia of the nose, which may take on irritation from different sources. In most cases, however, pollen will cause the exacerbation. I think Dr. Roe's method for determining the sensitive spot by the probe an excellent one.

ON THE DURATION OF CONTAGIOUSNESS AFTER ACUTE INFECTIOUS DISEASES.*

By ALFRED LUDLOW CARROLL, M. D., ETC.,
SECRETARY AND EXECUTIVE OFFICER, STATE BOARD OF HEALTH OF NEW YORK

UNDER most sanitary authorities a salutary regulation exists forbidding the return to school of any pupil convalescent from a contagious disease except upon a medical certificate that the danger of infection is past. And, aside from this very necessary precaution against the perpetuation and dissemination of infection in schools or through other public intercourse, our more private duties to our clients

* Read before the New York State Medical Association, November 18, 1884.

almost daily call on us to decide when it may be safe to permit the restoration to the family circle of some patient whom we have been carefully isolating in a separate chamber during the course of an acute infectious disorder. From many points of view, therefore, this inquiry is one of great practical importance to the public and to our profession; and yet, in the present state of our knowledge, it is one of the most difficult to answer. We know the limits of incubation of most of the infectious zymoses; we know something of the ætiology of many of them; we know much of their natural history, and we are unlearning much as regards their treatment. But in our narrow field of observation we know nothing of the wider and more momentous question. When do they cease to threaten others than the individual under our care? And in our preventive efforts we have for years gone on in blind empiricism, erring, perhaps—as it is the proper part of ignorance to do—on the side of over-cautiousness, but without any definite facts to guide us. Much time must elapse, and many accurate observations be made, before such facts can be established and fixed rules of conduct deduced from them; and my intention is, not to advance any new theories, but simply to present for consideration a subject which, in an assemblage such as this, may profitably serve as material for “collective investigation.”

In the consideration of this question we must theoretically exclude the retention of the several contagia by fomites. Without doubt, much perplexity has hitherto arisen from the undetermined part played by infected clothing resumed by the convalescent patient, or by other inanimate articles. For our present purpose we must assume that proper measures of disinfection have been pursued with regard to these, and that we have to deal solely with the body or excreta of the individual.

Another element of uncertainty lies in the “personal factor”—the varying susceptibility to infection of different persons, or of the same person at different times. Of a hundred unprotected persons exposed to the contagium of small-pox, or measles, or any other infectious zymosis, a considerable percentage will escape infection; but their immunity is, of course, no evidence that the transmissibility of the virus has ceased.

At the present day most of us, probably, are convinced that, in the majority, if not in all, of the communicable zymoses, certain forms of microphytes act, if not as the specific causes, at all events as the carriers of disease; and, from this point of view, our ultimate certitude as to the question at issue must come from further biological research into the life-history of the various pathogenic or pathophorous schizophytes and the latent vitality of their resting spores. But, in the mean time, our course must be shaped according to the best trained observations at our command.

The only attempt within my knowledge to formulate experience in respect of the duration of infectiousness is that of Dr. Miller, of Dundee,* whose tabulation is as follows:

Small-pox.....	14 days after termination of scabbing.
Typhus.....	28 days from inception.
Scarlet fever.....	7 weeks from inception.

Diphtheria.....	6 weeks from inception.
Whooping-cough.....	8 weeks from inception.
Measles.....	6 weeks from inception.

The first thing that strikes one about this table is the omission of any estimate of the duration of infectiveness in the discharges from diseases such as enteric fever or cholera; the second, the rather arbitrary assumption of intervals which in some instances may seem unnecessarily long.

In order to ascertain if there was any consensus of professional opinion regarding the points so often brought before me in my official position, I addressed, some months ago, a note of inquiry to several of the leading medical teachers and hospital physicians of this and other cities; whose names, for the present, I shall leave unmentioned, as their kind replies were intended to form the basis of a report to the State Board of Health. I may, however, briefly recapitulate the views presented in their valued communications.

SMALL-POX.—As to small-pox, there is practically unanimity in regarding the danger as existing until all crusts are removed; but a few incline to prolong even further the period of isolation. One of our most eminent teachers writes that “at least eight weeks should elapse . . . before a child that has been affected with it should be allowed to return to school.” On the other hand, a gentleman of wide sanitary experience apprehends but little danger from the crusts which sometimes linger under the thick skin of the soles and palms, provided that every scab is removed from the body and hair, and thorough cleansing of the surface effected. Other correspondents fix the duration of quarantine “during the whole of desquamation”; “until the cicatrices are fully healed”; “until all traces of the cutaneous affection have disappeared and everything is removed from the surface of the body by repeated ablutions”; and other replies are to the same effect; while one writer approves, in general terms, the rule of the Boston Board of Health, as regards all infectious disorders, that four weeks should elapse from the beginning of the last case of disease in the family before a patient should be allowed to attend school.

TYPHUS FEVER.—In relation to typhus, the responses are fewer and less in accord. One deems fomites the most important factor in the dissemination of the malady, while the rest lay stress on personal contagion. One regards it as “not contagious after a short interval”; a second advises segregation until repeated baths have followed the complete disappearance of the cutaneous exanthem; a third, somewhat indefinitely, would permit return to school “after complete recovery and disinfection.”

TYPHOID FEVER.—Those who believe in the direct personal contagiousness of enteric fever are few in number, and I fancy that nearly all of us will agree that the intestinal discharges are all with which preventive medicine has concern. Whether these retain their infectious properties during the whole process of the malady is a question still in uncertainty, and rendered more obscure by the apparent demonstration that the disorder may, under certain undetermined circumstances, be generated *de novo* from ordinary sources of filth-poisoning. At all events, isolation of the person seems unnecessary as soon as convalescence is complete.

* “British Medical Journal,” No. 1074, p. 173.

The same considerations will apply, I believe, to cholera, with the further remark that, if Koch's recent observations are correct, the germs of this disease appear to be short-lived than any other known species, being destroyed, not only by desiccation, but by the "scavenger-bacteria," which conquer them in the struggle for existence in the products of common decomposition.

DIPHTHERIA.—Diphtheria affords a wider debatable ground. To begin with, there are many (among whom my own experience forces me to class myself) who assign the first place in the pathogeny of diphtheria to filth-poisoning, and doubt its exceeding contagiousness. Of a number of persons exposed to the same pathogenic conditions, it is not surprising that several should succumb; but this is not convincing evidence of transmission from one to the other, and I have seen repeated instances where, despite intimate contact, the disease failed to extend after its introduction into places in proper sanitary condition.* Moreover, the experiments of Péter and Trousseau serve to show, at least, that diphtheria is not contagious under all circumstances. One of my correspondents, who has long had charge of a large hospital for children, believes this malady to be "feebly, if at all, contagious," and finds it quite safe to remit quarantine "after the disappearance of membranes"; a practical sanitarian, of national reputation, excluding fomites and filth in air or water, does not believe in personal contagion; a distinguished teacher in one of our metropolitan colleges doubts "its communicability, except by contact"; another, equally eminent, declares that contagiousness endures until the last trace of inflammation or infiltration secondary to the diphtheritic process has disappeared; a fourth would protract the duration of quarantine for a month, or, at least, three weeks, after all symptoms have abated, and would forbid return to school while any redness of the fauces or any coryza lingers. The discrepancy of opinions in this respect among the leaders of professional thought suffices to show the need of more definite data to guide our deliberations.

WHOOPING-COUGH.—In pertussis, all opinions agree, save one, that contagiousness ends when the cough loses its spasmodic character, the single doubtful view being that, as the danger is wholly from the breath of the patient, it can not be determined how long the cough may convey infection. It should be remembered, however, that a few writers have expressed doubts of the contagiousness of pertussis in any stage.

MEASLES.—With regard to measles I find equal diversity of views. One regards its contagium as very volatile, not long adhering to person or clothing, and permits the return of the patient to school in two weeks after convalescence; a second would defer liberation from quarantine until a week, at least, after desquamation; a third releases the patient when desquamation has ceased, or, in cases where no desquamation occurs, after twenty-one days; a fourth fixes eighteen days; a fifth believes the danger past when the febrile stage and eruption are gone. The majority measure

the time of isolation by the process of epidermal exfoliation.

SCARLATINA.—In scarlatina, also, we have opposing opinions, ranging from that which considers it as a pythogenic disease, slightly, if at all, contagious from the person, to that which holds the infection to be communicable by the pulmonary exhalations, the blood, the naso-pharyngeal secretions, even the urine, as well as by the epithelial scales. One of my correspondents thinks the infection remains so long attached to the person that quarantine should endure for eight weeks; another cites an example of transmission after six weeks of isolation followed by a change of clothing; the rest concur in releasing the patient after desquamation has ceased and the surface been thoroughly cleansed. Most of us, I dare say, have adopted this "rule of thumb." In my own practice, for some years, I had the patient frequently anointed with carbolized or thymolized vaseline, endeavored to maintain complete isolation until all desquamation was at an end, and then prescribed two or three thorough baths, including a careful washing of the hair and scalp. But on several occasions I found that the quarantine which I had ordained was considerably abbreviated by the parents or the patients themselves, and that children still furfuraceously desquamating after scarlatina or measles had indulged in social intercourse, or even returned to school, without conveying infection to their companions; and it occurred to me to wonder whether—granting that the exfoliated epithelial scales are the principal carriers of the contagion—all the successive crops of cast-off scales were acting as chariots for infective micro-organisms, or whether the later-arrived cells, as they rose from the deeper layer to become cornified in their turn and ejected, might not be quite free from taint. The same idea has evidently struck one of my most esteemed correspondents, who, speaking of quarantine during desquamation, adds that "forty days are sufficient," and that if, as sometimes happens, the scaling process seems to last much later, it is "no longer scarlatinal in character, but the result of dermatitis in general in a skin which has not regained its original health, without its being the seat of an infectious or contagious process."

I am quite aware that I ought to apologize for even this brief intrusion on your patience, when, instead of bringing any addition to your stock of knowledge, I come only to subtract from it, so to speak. But, forasmuch as "the promotion of public health" stands second on the list of objects of this association, I trust that I shall be pardoned for simply pointing out the uncertainty which exists in relation to one of the most needful means to promote public health, and for invoking your collective aid in elucidating the problem.

THE HYDROCHLORATE OF COCAINE IN GENITO-URINARY PROCEDURES.

By FESSENDEN N. OTIS, M. D.

My attention was first attracted to the probable value of the hydrochlorate of cocaine in genito-urinary troubles by my friend Professor C. R. Agnew, who gave me an early account of his gratifying success in operations on the eye

* *Vide* a paper by Dr. M. A. Avery, Assistant Physician to the Nursery and Child's Hospital, in the "N. Y. Medical Journal," February, 1882.

(subsequently published) and also kindly gave me sufficient of the two-per-cent. solution to try its effect on the mucous membrane of the urinary passages. Before a suitable case presented I received a note, November 6th, from Professor R. W. Pease, of Syracuse, giving me an account of his use in the urethra of a four-per-cent. solution in an operation for stricture an inch and a half back of the meatus on the day previous. "About twenty drops were used with a common dropper, stopping the progress of the solution backward by holding my finger on the urethra back of the stricture, and retaining it in the canal about eight minutes. The sensation was about nil. I ought to have retained it fifteen, and I think then the success would have been complete. . . . I have used the cocaine in a sensitive urethra, when catheterization was very painful, with charming results." He concludes: "I make no doubt in this new agent we have something that will entirely take the place of ether in all operations on the penile portion of the urethra." On the day following (November 7th), I dropped a few drops of the two-per-cent. solution received from Dr. Agnew into the first inch of a very sensitive urethra, holding it in ten minutes. I dilated the orifice from 27 mm. to 31 mm., preparatory to an operation for litholapaxy, which was to be done on the following day, and I did not wish to incise. The patient was very hyperæsthetic, but gave not the least evidence of pain during the operation. November 11th Dr. Coonley, of Staten Island, called with a patient suffering agony from frequent and difficult micturition. A stone in the bladder was suspected, but the doctor said it was impossible, and that intense pain was caused by the attempted introduction of instruments to get a satisfactory examination, and the patient was averse to the use of ether. He was obliged to urinate before anything was done, and it was at least five minutes, after passing a few drachms of urine, before the vesical tenesmus was fairly over. I then injected, with an ordinary penis-syringe, about fifteen drops of the solution given me by Dr. Agnew, and pressed it back into the urethra as far as possible. The patient retained it by pressure at the orifice for ten minutes. This was repeated, and at the end of the second ten minutes I introduced and passed a silver searcher (Thompson's) through the urethra (detecting a scale of calculous material *en route*) and into the bladder, without causing the least pain. I struck a stone in the bladder. I then took a large-sized Thompson's lithotrite and introduced it with some difficulty through the preputial orifice, which was not only contracted, but adherent to the orifice of the urethra. There were also two bands of stricture within the first inch of the canal, which impeded the progress of the lithotrite. By a little perseverance, however, I passed by these obstructions and carried the instrument into the bladder, grasped a stone of a diameter of one inch, and, while holding it, struck another stone, thus demonstrating the presence of at least two stones.

I then disengaged the lithotrite and withdrew it, tightly hugged in the anterior part of the canal. The patient stung, with great unction, that he felt not the slightest pain during the entire procedure. I then divided the preputial orifice freely, also the meatus and the strictures previously

mentioned, with a straight, blunt bistoury. Not the least flinching or sign of pain was observed, and the patient stated that he felt only a slight twinge when the second stricture was cut. This was fully ten minutes after the second introduction of the cocaine.

Delighted with the success in producing perfect local anæsthesia in this case, I immediately determined to use it in a case of hyperæsthetic urethra, associated with enlarged prostate, where, on account of the intolerance of the urethra to any sort of interference, the introduction of the catheter for emptying and washing of the bladder had been entirely suspended for several weeks. I had quite used up the solution given me by Dr. Agnew, and the leading drug-stores could not furnish it. I at last succeeded in getting half an ounce of a two-per-cent. solution. The patient (who was also a professional friend) was most anxious to have it tried, and was full of hope that this would enable him to have the necessary catheterization performed. The great dread of any interference made him insist that the solution should be introduced very slowly and gradually. It was fortunate that he did so, for, when not more than three or four drops were injected into the urethra, he became almost frantic with pain, and it was only after half an hour that the intense suffering caused by the injection passed entirely off. The action of this two-per-cent. solution, presumably of the same kind as that used in the previous case, made me fear that, as with other anæsthetics, there were idiosyncrasies in some persons that would contra-indicate its use. On making inquiry, I ascertained that there had been a number of cases met with where, a four-per-cent. solution of hydrochlorate of cocaine being used in the eye, a period of thirty or forty seconds of quite sharp irritation preceded the anæsthetic effect, and, also, that at least one case of sharp urethritis had been directly caused by its application to the urethra. On making close inquiry, I at last ascertained that the druggist from whom I obtained the solution, having none of the hydrochlorate on hand, *had dissolved the alkaloid in hydrochloric acid*, and had used this extemporaneous hydrochlorate for my solution.* Having soon the good fortune to obtain a small bottle of Merck's crystals of the hydrochlorate of cocaine, I made a two-per-cent. solution with distilled water, in which two per cent. of biborate of sodium had been dissolved, and on a second trial in the same case, where so much suffering was caused through the impurity of the solution, I succeeded in applying it to the urethra, as in the previous case, and in passing a catheter, drawing off the urine and washing out the bladder without the least pain. On Thursday last, November 20th, in my clinique at the College of Physicians and Surgeons, I introduced a similar solution into a very sensitive urethra associated with senile hypertrophy of the prostate. A preliminary attempt to pass a catheter caused manifest pain. After the retention of the four-per-cent. solution of hydrochlorate of cocaine for ten

* I subsequently tasted the cork of the phial containing the solution, and found that a sharp stinging sensation quickly followed, and continued to be felt for ten or fifteen minutes. On applying Merck's four-per-cent. solution of cocaine to my tongue, in the same way, only a slight furry feeling was produced, reminding me of a weak solution of aconite.

minutes in the urethra, the catheter was passed through the urethra, and subsequently the bladder was examined for stone, and not the least complaint of pain in the urethra was made.

On the 23d inst. I introduced a four-per-cent. solution into a fairly tolerant urethra to a depth of four inches, and retained it ten minutes. I then divided with my dilating urethrotome a dense stricture half an inch broad and five millimetres thick without the least shrinking on the part of the patient, who stated that he had only the feeling of distension, and not the slightest sense of pain during or subsequent to the operation. I have made several experiments since, and find that the best mode of introducing the cocaine solution for relief of irritable urethra, especially when associated with prostatic trouble, is to attach a tight-fitting half-ounce penis-syringe to an open-end rubber catheter of eighteen or twenty mm. in circumference. After pouring the solution into a small graduate, draw a sufficient quantity up into the catheter. Introduce it for a half-inch, or until the patient complains of pain, then press down the piston, gradually driving a few drops in advance of the catheter, rubbing it along with the finger, waiting for three or five minutes, then passing it down about two inches farther, and repeating the process of coaxing the fluid back until finally the end of the catheter enters the bladder, consuming altogether about fifteen minutes.

It will, I think, be proved that the greatest good will come from the use of the cocaine in the cases of irritability of the deep urethra associated with prostatic disease. In these cases the passage of a catheter, so essential to the comfort and even the life of the patient, is frequently rendered painful, and not rarely impossible, by spasm of the deep urethra. The use of cocaine promises quickly to reduce both the pain and the spasm, and allow of the easy passage of the instrument, and this, too, by a procedure quite within the province of an intelligent patient to use after proper instruction. A four-per-cent. solution of the hydrochlorate of cocaine in almond-oil makes an excellent lubricant for urethral instruments, and I think may prove even better than the watery solution for applications to the urethra. Its use in this way, in a few cases, has been very satisfactory.

The value of the solution of hydrochlorate of cocaine will be equally found in examinations of and operations upon the irritable anus and rectum. Yesterday I had occasion to examine a case of deep and irritable ulcer involving the tissues around the anus fully three inches in circumference to a depth of fully half an inch, and extending inward an inch or more beyond the margin of the external sphincter. The patient was an old woman of sixty, who had been worn to the last degree of irritability by nearly two months of suffering. After painting the surface of the ulcer with a four-per-cent. solution for ten minutes, I then introduced a bivalve speculum and exposed the whole inner surface, and cauterized it thoroughly, without the least expression of pain from the patient.

108 WEST THIRTY-FOURTH STREET, November 29, 1884.

THE SURGICAL MANAGEMENT OF RHACHITIC DEFORMITIES OF THE LOWER EXTREMITIES.

By V. P. GIBNEY, A. M., M. D.,
PROFESSOR OF ORTHOPÆDIC SURGERY IN THE NEW YORK POLYCLINIC.

(Concluded from page 609.)

A French writer on these deformities teaches that the best way is the quickest way, and a simple fracture can often be made in marked cases of deformity by manual force, while the treatment of the fracture is very simple. The plaster splint, as devised and so successfully used by Dr. Little, of this city, places these lesions of our own making under absolute control. Even the plaster-of-Paris bandage, when smoothly and neatly applied, serves to bring about perfect union. Other means of dressing will, of course, suggest themselves as one's taste inclines.

In correcting genu valgum, this manual force is often practiced, and is known as Delore's method, or *osteoclasie manuelle*. Epiphyseal fractures are produced frequently, ligaments are torn, and joints rendered very unsteady. Dr. Macewen concludes a survey of the method of *redressement forcé* by the following remarks:

"It may safely be concluded that *osteoclasie manuelle*, or *mécanique*, has served its time, and can not be practiced in the presence of the more exact methods of the present day."

From my own experience in redressing genu valgum in this way, and from the drift of sentiment, oral and written, I am well assured that Macewen's conclusion in 1880—the date of the publication of his work—will be warmly seconded at the close of 1884.

Among the more enthusiastic advocates of mechanical appliances for the gradual correction of these deformities, Dr. William J. Little, of London, stands at the head. The orthopædist, as a rule, is more or less committed to the employment of springs in these as well as in other deformities.

Certain cases demand apparatus, and this is sometimes an important point in diagnosis. Surgeons who have performed osteotomy very extensively agree upon that age when the bones yield to a moderate manual force as the age for the employment of springs. Dr. Poore, for instance, believes that, in a rickety child, yielding of the bones will be felt up to the fifth or sixth year. This author is not so much opposed to the use of splints as Dr. Macewen is. The latter, speaking of their use, says: "Good results, in isolated cases, are spoken of as having occurred; personally I have not seen any" ("Osteotomy," p. 93). In this city, at least, I am sure that the custom is to apply springs to children thus afflicted at any time between the second and eighth year.

The rule at the Forty-second Street Hospital is to reject cases in patients over three years of age. The rule, however, is honored more in the breach than in the observance. Clinically, five years seems to be the limit at this institution. My own rule is to employ springs, if I find the bones can be sprung with moderate manual force. We can test the bone in this manner with very little pain. I am refer-

ring now to bow-legs. If I find the femur curved, and the inner condyle unusually long in a case of knock-knee, I test with my hands the ligaments of the knee and the femoral curve, and am guided in my selection of cases for apparatus. The age beyond which I find this test failing is from four to five years. While an interne at the hospital, I had abundant opportunity of testing limbs, and the tracings on my records made from time to time in cases under treatment but confirm me in the adoption of this test for my guide. My friend, Dr. Poore, I find, is guided by the same test. At the out-door department of the hospital it is customary to refer to other hospitals, for osteotomy, children over four years of age, in whom these deformities are aggravated.

At the New York Orthopædic Dispensary very few cases are rejected, judging from Dr. Shaffer's very instructive paper on this subject published in "The American Journal of Obstetrics and Diseases of Women and Children" for July, 1881.

Dr. Little assigns no limit as regards age. He does what many of us do—viz., use splints first, and, these failing within a few months, resort to operation. His success, however, prompts him to undertake cases that many orthopædists in this country would relegate to the domain of operative surgery.

At this point a discussion as to the forms of apparatus employed, the advantages alleged for each, and the principles involved, will help to determine what cases can be corrected.

All the springs now in use are constructed, I believe, on one principle. This principle is force brought to bear against the convexity of the curve at its apex. One class of springs is intended to exert moderate but continuous pressure, while another class is intended to exert exaggerated pressure for a few seconds or minutes (Shaffer) in the direction opposed to the deformity.

If it is necessary to confine a patient to bed, an ordinary side-splint serves an admirable purpose; for with this a roller or rubber bandage, or straps and buckle, will exert as much pressure as can be tolerated. Dr. Little employs continuous pressure, and he represents the views of the larger proportion by far of the orthopædic surgeons. Dr. Shaffer represents the views of those who advocate the exaggerated momentary pressure.

About the simplest form of portable springs for continuous pressure are those in use at the Forty-second Street hospital. Concerning their efficiency I can speak quite positively.

The points of counter-pressure in a case of genu valgum are the trochanter and the outer ankle, and in a case of bow-legs the inner condyle of the femur, or the space immediately above this and the inner ankle. The ankle in each instance is protected by a steel foot-plate and heel-cup, which is worn within the shoe. The two vertical pieces are of bar steel without special polish, and are joined at the top by a semicircular band passing about the posterior surface of the thigh for knock-knees and the calf for bow-legs. At the lower end they are fastened by a rivet with a washer, making a free joint opposite the ankle. The apparatus is

held in position by straps continuous with this semicircular steel band and passing over the front of the limb, to fasten by a buckle or knob to the other end of the band. The foot is held in place by an instep-pad, the straps from which pass on either side through the space between the foot-plate and heel-band, to be brought over the outer side of the upright bars and tied on the pad already mentioned. At the upper end of the vertical bar for counter-pressure is a pad. Pressure is brought to bear now against the convexity of the curve by means of a broad band of canvas or leather, fastened to the outer vertical bar for knock-knees, to the inner for bow-legs, which band is brought now about the limb to lace in front. In other words, this band or belt passes, in the case of knock-knees, on the outer side of the outer bar and inner side of the inner bar, and *vice versa* for bow-legs.

These springs can be covered with material to suit one's taste, and finished to please the most fastidious. In ordering apparatus from any surgical-instrument maker, one should give a drawing and measurements, aiming to meet the therapeutic indications that the case presents.

Catalogues can be readily obtained from any of the prominent instrument-makers, and modifications of apparatus figured will always be made when ordered.

I have thus described one form of appliance, with the idea of giving the general underlying principle rather than of recommending any special make.

The splint employed at the New York Orthopædic Dispensary and Hospital is fully described by Dr. Shaffer in the paper to which I have already referred. Dr. Poore finds, by consulting published statistics, that the proportion of cures in genu valgum is not quite thirty per cent.

I very much regret that I have nothing statistical to contribute bearing upon the percentage of cures. To secure reliable data of this kind more time is required than I have at my disposal.

OSTEOCLASIS.—This operation has certainly not become popular in this country. Naturally one would prefer a simple fracture to a compound, and yet, for some reason, comparatively few surgeons resort to osteoclasis.

The perfection of French instruments has rendered the operation a popular one in France. Osteoclasts in this country do not give the results we are led to expect. Until we can have as complete an instrument as that of Robin, of Lyons, osteotomy will continue to be the operation for correction of femoral and tibial curves.

The various instruments are fully described in Dr. Poore's work, and need not be described in detail this evening.

OSTEOTOMY.—This operation has become applicable to nearly all rhachitic deformities of the extremities. There are very few surgeons but have become familiar with it, either for knock-knee or for bow-legs. The literature is abundant, and the instruments employed, as well as the mode of operating, are familiar to all. I certainly would not attempt to tell the fellows of this Academy how to operate when whole chapters in recent works discuss this point in the fullest of detail. It is with results that I shall deal, and, in speaking of those for the relief of genu valgum, I can do no better than ask you to note with me some statistics Dr. Macewen presented at the recent meeting of the

International Medical Congress held in Copenhagen. In eight hundred and twenty personal supra-condyloid osteotomies there were only eight cases in which suppurative took place, and in six of these the cause was attributed to extra force applied under accidental circumstances. He had only one relapse; had hæmorrhage in none. Five died, but in not one was the fatal result due to the operation. In five hundred and eighty additional cases collected from British surgeons he finds hæmorrhage in only two instances, supuration in forty, and relapse in five, while in two there was ankylosis, and three died as a result of the operation.

His personal operations were conducted under the spray and with strict Listerian precautions. For full details the "Lancet" for September 27th can be consulted. There is also an excellent abstract in the "Medical News" for November 1st. From this abstract I find that profuse, and even fatal, bleeding may attend this procedure.

Langton, in the "Lancet" for March 29, 1884, records a "death after amputation of the thigh on account of gangrene consequent upon ligation of the popliteal artery, which had been punctured by a sharp spicula of bone which projected from the lower fragment."

McGill, in the "Lancet" for May 17th of this year, records a case in which the popliteal artery was completely divided, the patient making a good recovery after ligation of both ends.

Howard Marsh ("British Medical Journal," April 5, 1884) wounded the anastomotica magna, but successfully secured it on the seventh day. A friend in this city tells me that he has divided this artery. In a case of my own I had most alarming hæmorrhage from the bone itself, and succeeded only in controlling it by packing a sponge covered with iodoform between the cut surfaces. This is the only case in which I have had any hæmorrhage that gave the least annoyance. The case in which I had the bone hæmorrhage was in an Italian girl, aged seven years and a half. I did the supra-condyloid operation on account of a marked symmetrical antero-lateral curvature of the femora, and, but for this annoying hæmorrhage, would have also done Shede's operation on the tibiae, inasmuch as sharp tibial nodes, or exostoses, existed on the anterior and inner aspects of these bones at the junction of the upper with the middle third. The result has been good, so far as the femoral curves are concerned, but there is still a well-marked genu valgum dependent on the tibial curves. A detailed account of my osteotomies would be premature, as I have only enjoyed this privilege during the present year.

In February I did a double cuneiform osteotomy, in private practice, in a case that I had had under mechanical treatment for twelve months. And let me here remark that I have never seen an anterior tibial curve corrected by apparatus. This is pre-eminently one of the rhachitic deformities that mechanical appliances will not, so far as my observation goes, make any impression upon. The result of the cuneiform osteotomy was good, and all appliances have long since been discarded. In only one instance have I had a hospital case to treat, and it is to my friends, Dr. Chauveau and Dr. Adam, that I am indebted for the courtesies of the French Hospital.

In March I operated on a nineteen-year-old lad for the relief of bow-legs, and the section through his tibiae was tedious in the extreme. The relief has been greater than was anticipated; for not only is the deformity entirely overcome, but his gait is far better than it ever was. [The accompanying sketches were made by Dr. Van Shaik on March 11th, the day of operation, and on August 18th, four months after removal of all support.]

It is interesting to note that I have done nine linear osteotomies and two cuneiform osteotomies, during the past six months, at the Polyclinic, and sent the patients home as soon as the plaster dressing had become hard enough. In none was there any temperature above 102° F.

In a supra-condyloid osteotomy I have had a unique accident, so far as I can learn. The accident was a paralysis of the external peroneal nerve, first appearing at the end of the third week. The operation was done on August 7th, and on September 2d, having seen the case several times in the interval, I fancied that there was a slight paralysis of the anterior tibial group of muscles. A more careful examination was instituted on September 4th, and it required a very strong faradaic current to get any response in this group. On the 17th Dr. Starr tested the case electrically, and found faradaic contractility absent in the anterior tibial group, very much diminished in the peroneals and posterior tibial. In the anterior tibial group he found with galvanism the reaction of degeneration. The whole leg, and indeed the thigh, seemed powerless. Under electrical treatment, and apparatus to retain the foot in normal position, the limb has been restored. November 8th the cure was nearly complete.

In view of the invasion of the paralysis after three weeks had elapsed, and its disappearance two months later, I can see no other explanation than the injury to the nerve by the occurrence of callus.

The lessons I have learned from my own operations are:

1. Exaggerate the correction of deformity.
2. Examine the limb at the end of a week to ascertain whether the amount of correction gained is the amount desired.
3. Do not hesitate to refracture by manual force if it is necessary.
4. With strict attention to details in operating, and in the use of good plaster-of-Paris bandages well applied, cases

can be treated in a dispensary nearly as well as in a hospital.

5. In dispensary cases do all the operating you propose doing at one sitting.

I am still convinced that one loses nothing by following Lister as closely as it is possible to follow. If cleanliness in all particulars is Listerism, then be cleanly in every particular. I am satisfied that the best results are obtained in this way, and I propose to leave no stone unturned to secure the best possible results. Three months' support, in some form of splint, subsequent to the operation, is not too long.

The paper of Macewen at the International Congress compelled all men to admit that the supra-condyloid operation was *par excellence* the operation for genu valgum.

I have made no reference to the instruments employed, for the reason that the osteotome either of Macewen or Poore is the only one used.

As I am completing this paper, my friend, Dr. Shrady, permits me to inspect his new saw, and it seems that it is all that could be desired in a saw. The chisel or osteotome has taken the place of the saw, because no bone-dust is left to interfere with the healing of the bone.

If I have not given credit to the work of surgeons in this city, it is because I expect them here this evening to speak for themselves.

Book Notices.

Lectures on the Principles and Practice of Medicine. Delivered in Chicago Medical College, Medical Department of the Northwestern University. By NATHAN SMITH DAVIS, A. M., M. D., LL. D., Dean of the Faculty, and Professor of the Principles and Practice of Medicine and Clinical Medicine, in Chicago Medical College; Senior Physician to the Mercy Hospital, Chicago, etc. Chicago: Jansen, McClurg & Co., 1884. Pp. x-896.

We do not need the author's assurance that he has been for many years a practical teacher of medicine, for even a cursory glance at the work will assure the reader that it is the product of years of thought and experience. Treatises on the subject are by no means few in number, but there will never be so many that we can not heartily welcome another book like this. It would seem almost impossible to write anything new and interesting upon such a well-worn subject as the practice of medicine, yet Dr. Davis has displayed great originality, both in the arrangement and in the subject-matter of his work.

We can not enter upon a detailed notice of its many excellent points, or state at length wherein it differs from other works of the same class. But we would not have it understood that our praise is entirely unqualified. The author is a practitioner "of the old school," and, while he keeps abreast of the latest theories, he still clings to some of the ancient methods of classification. It seems rather odd at the present time to read about "susceptibility," "vital affinity," and "fluxes," but let us not judge from the writer's retention of these old terms that he is not conversant with the newest fashions of phraseology—far from it.

To describe the book briefly, we may say that it consists of

two parts; the first part, which includes about forty pages, treating of health and disease, "general processes and complex functions," medicines, and diagnosis. This is by far the least pleasing part of the volume, and, if the truth were told, it is to be feared that the students who listened to these introductory lectures must often have been somewhat puzzled in their attempts to catch the speaker's meaning. But, when the author enters upon the discussion of individual diseases and their treatment, we feel that he is more at ease. His classification is rather different from that adopted in most text-books. Beginning Part II with "General Diseases," he treats first of fevers, and then of scrofula, leucocythæmia, carcinoma and syphilis, rheumatism, and gout.

Typhoid fever is discussed exhaustively, no fewer than five long lectures being devoted to it; we can not say as much for intermittent fever, which is dismissed with barely two pages. Lectures XXXIII to XCII, inclusive, cover the subject of "Local Diseases," under which are included, first, affections of the brain and spinal cord, then pulmonary and cardiac diseases, morbid conditions of the abdominal organs, and, lastly, a class which the author calls "neuroses." Under the last-mentioned head he treats of apoplexy, hemiplegia (as if the two were separate affections), epilepsy, chorea, and functional nervous diseases.

After two lectures devoted to "Mental Derangements," Dr. Davis discusses what he calls "Miscellaneous Diseases," under which are included spasmodic asthma, angina pectoris, exophthalmic goitre, fatty heart, diabetes, and verminous diseases—a miscellany in every sense of the word! The book concludes with a vigorous lecture on alcohol as a therapeutic agent, in which the writer decidedly opposes the estimate generally held of the drug in that capacity.

In looking over the volume, we are struck with the fact that it is not evenly written; but this must be regarded as in some degree unavoidable when we remember that it is simply a series of extemporaneous lectures. Dr. Davis's strength lies not so much in his statements of theories as in his descriptions of disease and its treatment; although he is thoroughly informed in modern pathology, he is not a pathologist, but a practical physician. The value of his book to practitioners will lie in its clear style, its forcible presentation of important facts, and the admirable judgment displayed in the matter of treatment.

BOOKS AND PAMPHLETS RECEIVED.

Lehrbuch der Physiologie für akademische Vorlesungen und zum Selbststudium. Begründet von Rud. Wagner, fortgeführt von Otto Funke, neu herausgegeben von Dr. A. Gruenhagen, Professor der medicin. Physik an der Universität zu Königsberg i-Pr. Siebente, neu bearbeitete Auflage, mit etwa zweihundertundfünfzig in den Text eingedruckten Holzschnitten. Dritte Lieferung. Hamburg und Leipzig: Leopold Voss, 1884. Pp. 321 to 480, inclusive.

Transactions of the Academy of Medicine in Ireland. Vol. II. Edited by William Thomson, M. A., F. R. C. S., General Secretary, Surgeon to the Richmond Hospital, Dublin. Dublin: Fannin & Co., 1884. Pp. xxv-504.

Ciencia y Arte de los Partos. Por el Doctor Guillermo Thompson Lusk, Profesor de Obstetricia y Enfermedades de las Mujeres y de los Niños en el Hospital de Buenavista de Nueva York, etc. Traducida de la Segunda Edición Norte Americana por Federico Toledo, Licenciado en Medicina y Cirugía, Madrid. Nueva York: D. Appleton y Ca., 1884. Pp. 801.

THE
NEW YORK MEDICAL JOURNAL,
A Weekly Review of Medicine.

Published by
D. APPLETON & CO.

Edited by
FRANK P. FOSTER, M. D.

NEW YORK, SATURDAY, DECEMBER 6, 1884.

THE NEW LOCAL ANÆSTHETIC.

FOR several weeks past the medical press, including this journal, has teemed with testimony to the wonderful anæsthetic effects of the hydrochlorate of cocaine. Under ordinary circumstances, we should have waited for as many months to elapse before formally granting the truth of such allegations as are commonly put forth in behalf of any new remedy. But, although the available supply of the salt has thus far continued to be exceedingly limited, but a very small quantity has been needed to establish its marvelous power, and that little has been used to good purpose. We have no longer any hesitation, therefore, in proclaiming the announcement of the anæsthetic power of cocaine to be the most important that has been made in therapeutics since Morton astonished the world with his demonstration of the power of ether—the first and still the best of general anæsthetics.

Until within the past few weeks, coca had been known and used chiefly—almost exclusively—as a stimulant, and it is therefore not a little remarkable that its alkaloid should suddenly have made a brilliant reputation as a nullifier, for the time being, of the function of sentient nerves. On the other hand, as Dr. Squibb pointedly remarks, in his admirable article on the subject, in the November number of the "Ephemeris," it is almost as unaccountable that the full anæsthetic power of the drug was not brought to light before, seeing that its dilating effect on the pupil was well known, and that it was even in use to some extent by the laryngologists to benumb the throat so that it would admit of readier manipulation. But this latter consideration should not detract in the least from the credit to be given the medical student, Koller, for his discovery.

Even if it had turned out to be the case, as was at first supposed, that the anæsthetic effect was limited to the tissues that had actually imbibed the solution—and therefore to such small areas that the anæsthesia would scarcely have been available outside of ophthalmic practice—the great advantage of the agent would have remained unquestioned. That the range of its application would have been thus hampered is not disproved, practically speaking, by even so startling a fact as that laparotomy has been performed with no other anæsthesia than that produced by it, for we take it that the performance of abdominal section under local anæsthesia is at best but a curiosity, and not at all likely to become a settled practice. What is possible is not always the most desirable, and it seems to us extremely doubtful if surgeons will be willing to dispense with general anæsthesia as a rule in major operations. Leaving these out of account, however, there is a wide range of operative procedures in which it is necessary to have a considerable area anæsthe-

tized, but in which there is no need of abolishing the patient's consciousness. These cases could not well have been met by a local anæsthetic acting merely by imbibition, and it is for that reason that the newly discovered fact that the parts supplied by a sensory nerve may be made insensitive by an injection of cocaine in the immediate neighborhood of the trunk of that nerve is of an importance that can not be overestimated. That discovery seems to have been well established by the experiments performed by Dr. Halsted and Dr. Hall, recounted in the latter gentleman's letter, which we publish in another column; and we must not omit to credit Dr. Burke, of South Norwalk, Conn., with having practically hit upon the same idea, as may be gathered from his letter which we published last week.

No doubt much yet remains to be done in the way of experiment and observation before the precise sphere of the new anæsthetic can be defined, and it would be prudent for those who may undertake to furnish us with these data not to count too much upon the innocuousness of the drug, for it should be noted that Dr. Hall experienced marked constitutional symptoms from an injection of thirty-two minims of a four-per-cent. solution of the hydrochlorate. While caution is to be observed, therefore, the teachings of even our present limited experience with cocaine ought to go far toward silencing the senseless babble so often indulged in about the uselessness of experimenting with the comparatively unknown substances of the vegetable *materia medica*. Here was an alkaloid supposed to be well-nigh worthless, but it has suddenly been raised to the first rank. Who can doubt that our knowledge of its power would have been considerably delayed but for the work of the pharmacists? Had the Darmstadt laboratory remained, even up to the present time, the sole available source of its supply, much of what has already been accomplished with cocaine would unquestionably have been blocked by the sheer impossibility of obtaining the drug. We have all along been loath to believe that American chemists were unable to produce it, and we are gratified to be able to note that the potent product with which Dr. Halsted and Dr. Hall conducted their experiments was made by Messrs. Parke, Davis & Co. This aspect of the matter is not without its economic bearings, for we learn from Dr. Squibb's article that one of the chief obstacles to the production of the drug on a large scale in this country is the enormous tax which the Government sees fit to levy on alcohol and ether, those substances being the chief solvents used in the separation of the alkaloid.

MINOR PARAGRAPHS.

KOCH'S REPLY TO HIS OPPONENTS.

THE "Deutsche Medizinal-Zeitung" publishes a long letter by Koch, in which he replies to the objections urged against the specific character of the comma bacillus, and discusses chiefly the counter-experiments by Lewis and Finkler and Prior. We have not space to quote the letter at length, but would refer the reader to the original. The main point urged is, that all the gentlemen who have questioned the writer's results have not shown sufficient care in the conduct of their own experiments. He sees no reason as yet to lose faith in the importance of his discovery. One statement which he makes is of great weight

—that Rietsch and Nicati's experiments regarding the artificial production of cholera in the lower animals have been repeated with success in his own laboratory.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 2, 1884:

DISEASES.	Week ending Nov. 25.		Week ending Dec. 2.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	42	13	45	12
Scarlet Fever.....	61	15	50	12
Cerebro-spinal meningitis.....	1	1	9	9
Measles.....	127	21	111	20
Diphtheria.....	73	25	59	33
Yellow Fever.....	1	1	0	0

The Health Department of the City of New York, having lately been induced by the Grand Jury to modify the conservative view it had taken for some time past of the storage of vast accumulations of stable manure in the city, has adopted the following resolution: "*Resolved*, That the Sanitary Superintendent be and is hereby directed to cause an inspection to be made daily of all places where manure has been dumped, and to report whether the regulations in respect to dumping and storing of stable manure and straw in this city are complied with; also whether due progress is made in the removal of all accumulations of stable manure and straw by the owners of the same."

A Sanitary Convention, under the auspices of the State Board of Health of Michigan, was held at East Saginaw on Tuesday and Wednesday, the 2d and 3d inst. A number of papers of a popular character were read, among which we note the following: "Typhoid Fever and Low Water in Wells," by Dr. Henry B. Baker, the Secretary of the State Board; "Disposal of Waste Matter," by Dr. J. H. Kellogg, of Battle Creek; "Adulterations found in Common Foods," by Dr. V. C. Vaughan, of Ann Arbor; "Sewerage and Drainage in Relation to Public Health," by Dr. Henry F. Lyster, of Detroit; and "The Water Supply of East Saginaw," by the Hon. W. L. Weber, Dr. C. H. Eames, and Dr. R. C. Kedzie.

The Health of the State of New York.—The "Monthly Bulletin of the New York State Board of Health," for October, 1884, shows a reported mortality for the month of 5,871, being the smallest since June. The percentage of infant mortality was 41.0, of that from acute respiratory diseases 10.8, from consumption 15.4, from diarrhoeal diseases 11.1, from croup and diphtheria 7.1, from typhoid fever 3.0, and from all other zymotic diseases 5.2.

The Endemic in Virginia and Kentucky.—Concerning the outbreak of disease among the inhabitants of certain mountain counties adjoining the boundary between the States of Virginia and Kentucky, a correspondent writes us that his understanding of the situation is as follows: "The long drought, which began the 1st of August and has continued up to this time, dried up the springs and wells, also some of the creeks and rivers. On account of the great scarcity of water, many families were compelled to obtain their scanty supplies from stagnant pools in the exposed beds of creeks and rivers, and from hitherto unused mineral springs, the bitter purgative waters of which irritated the stomach and bowels, and produced diarrhoea, bloody flux, and in many instances death. Add to this impure water-supply insufficient food, and you have, no doubt, the prime fac-

tors of the outbreak. In proof that bad water has been the chief cause of the sickness, I give the current fact that, after a sufficient rainfall to raise the water in springs and wells, there followed immediately fewer cases of the disease and milder symptoms."

A Brooklyn Gynaecological Sanitarium.—We learn that Dr. Skene and Dr. Thallon have removed their sanitarium to a new building in President Street, Prospect Park Heights, a situation that seems to combine attractive surroundings with manifest sanitary advantages.

Sanitary Work in Naples, it is reported, is to be carried on vigorously, the Italian Government having appropriated nearly \$20,000,000 for the purpose.

The International Medical Congress of 1887.—The following-named gentlemen have been chosen officers of the congress: Dr. Austin Flint, Sr., of New York, President; Dr. Alfred Stillé, of Philadelphia, Dr. Henry I. Bowditch, of Boston, and Dr. R. P. Howard, of Montreal, Canada, Vice-Presidents; Dr. John S. Billings, of the army, Secretary-General; Dr. J. M. Browne, of the navy, Treasurer; and Dr. I. Minis Hays, of Philadelphia, Dr. A. Jacobi, of New York, Dr. Christopher Johnston, of Baltimore, and Dr. S. C. Busey, of Washington, members of the Executive Committee (besides the President, the Secretary-General, and the Treasurer). We are indebted to the Secretary-General for a copy of a circular giving further information, which we shall lay before our readers hereafter.

The New York Polyclinic.—Dr. W. B. DeGarmo has been appointed assistant to the chair of orthopaedic surgery. During the present session he will occupy the hour from 3 to 4 P. M., every Wednesday, in demonstrating the methods of making and applying the various apparatuses for the relief of hernia.

An Aspiring Midwife, plying her trade in Paris, advertises herself, according to the "*Progrès médical*," by distributing a handbill which reads as follows: "Plus d'héritiers antipathiques. *Experientia magister artium*. Guérison infaillible de la stérilité par la fécondation artificielle. Procréation des sexes à volonté. Prix accessible à toutes les bourses. Sage-femme, diplôme supérieur. Consultations tous les jours de midi à 2 heures."

The late Professor Pacini's Manuscripts, we learn from the "*Gazzetta degli Ospitali*," have been purchased by the Italian Minister of Public Instruction, and his unpublished memoirs on the cholera are to be edited by Dr. A. Bianchi.

A Caution.—Gentlemen who think of subscribing to this journal are cautioned against having any dealings with one P. M. Courtenay, who has lately been conducting his operations in Maine and New Hampshire.

The Death of Dr. William H. King, formerly of Providence, R. I., took place on the 16th inst., in California, whither Dr. King went about five years ago, on account of the state of his health. He was a graduate of the Bellevue Hospital Medical College, and practiced in Providence about five years, during which time he occupied several official positions.

A Statue of Sir Erasmus Wilson, in bronze, says the "*Medical Times and Gazette*," is to be erected outside the Margate Infirmary. It will represent him clad in his robes of office as president of the Royal College of Surgeons.

M. Pasteur, says the "*Lancet*," is reported to be about to proceed to Rio Janeiro in order to study the yellow fever.

Hydrophobia, according to a press dispatch, is prevailing in Vienna at the present time.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 23, 1884, to November 29, 1884:*

LORING, L. G., Captain and Assistant Surgeon. Assigned to duty as Post Surgeon, San Diego Barracks, San Diego, Cal. S. O. 135, Department of California, November 19, 1884.

WILSON, GEORGE F., First Lieutenant and Assistant Surgeon. Granted one month's leave of absence, from November 20th. (Vancouver Barracks, Wyoming Territory.) S. O. 180, Department of the Columbia, November 18, 1884.

WALES, PHILIP G., First Lieutenant and Assistant Surgeon. Now at Fort Cœur d'Alène, Idaho Territory, ordered for temporary duty at Vancouver Barracks, Wyoming Territory. S. O. 179, Department of the Columbia, November 17, 1884.

Society Meetings for the Coming Week:

MONDAY, December 8th: New York Ophthalmological Society (private); New York Medico-Historical Society (private); Boston Society for Medical Improvement; Gynecological Society of Boston; Burlington, Vt., Medical and Surgical Club.

TUESDAY, December 9th: New York Medical Union (private); New York Surgical Society; Newark, N. J., Medical Association (private); Trenton, N. J., Medical Association (private); Medical Societies of the Counties of Morris, N. J., and Penobscot, Me.

WEDNESDAY, December 10th: New York Pathological Society; American Microscopical Society of the City of New York; Medico-Legal Society, New York (election); Medical Societies of the Counties of Cayuga, Chemung, Cortlandt, and Montgomery, N. Y., and Middlesex, N. J.; Pittsfield, Mass., Medical Association (private); Strafford District, N. H., Medical Society.

THURSDAY, December 11th: Harlem Medical Association of the City of New York; New York Laryngological Society (private); Society of Medical Jurisprudence and State Medicine, New York (election); Brooklyn Pathological Society; South Boston, Mass., Medical Club (private); Medical Society of the County of Addison, Vt.

FRIDAY, December 12th: Yorkville Medical Association, New York (private); Medical Society of the Town of Saugerties.

SATURDAY, December 13th: New York Medical and Surgical Society (private).

Letters to the Editor.

HYDROCHLORATE OF COCAINE.

17 EAST FORTY-NINTH STREET, November 26, 1884.

To the Editor of the New York Medical Journal:

SIR: Wishing to use the hydrochlorate of cocaine in some small operations at the Roosevelt Hospital Out-door Department, I made some experiments on myself, to determine the best mode of using it. The preparation was a four-per-cent. solution made by Parke, Davis & Co. Injecting subcutaneously six minims on the dorsal surface of the forearm, at the junction of the middle and upper thirds, near the ulnar border, caused complete loss of sensation over an area extending downward as far as the lower end of the ulna, from three quarters of an inch to an inch wide above, and half an inch wide below, obviously following the distribution of a cutaneous branch of the ulnar nerve. There was no diminution of sensibility above the point at which the needle was introduced. A number of subsequent

experiments showed that the anæsthesia extended over the region supplied by the cutaneous nerves near or into which the injection was made. Thus, in a number of experiments made by Dr. Halsted and myself, we have found that, injected subcutaneously into the leg or forearm, not in the neighborhood of any large nerve-trunk, it will cause anæsthesia for a distance of two or three inches below the point of injection. An injection into the musculo-cutaneous nerve of the leg, at the point where it pierces the deep fascia, caused anæsthesia over all that portion of the leg and foot supplied by this nerve. An injection of eight minims into my left ulnar nerve at the elbow had no effect. An injection of thirty-two minims into the right ulnar nerve at the elbow caused, in two or three minutes, numbness and tingling down the forearm and little finger, and in five or six minutes anæsthesia extending down the ulnar border of the forearm and hand and over the little finger, with much reduction of the sensibility on the ulnar border of the ring-finger. There was an anæsthetic area over the olecranon and the posterior surface of the external condyle, which we should not expect to be supplied by the ulnar nerve. There was no apparent diminution of muscular power, and no anæsthesia of the skin at the point where the injection was given. We have noticed that, when the needle is thrust into the deeper layers of the subcutaneous connective tissue, there is usually no loss of sensibility at the point where the needle was introduced.

With the anæsthesia, marked constitutional symptoms appeared; about six minutes after the injection there was giddiness, at first slight, then well marked, so that I could not walk without staggering; and finally there was quite severe nausea, which would have been much worse, I think, had not the stomach been empty. At the same time, the skin was covered with cold perspiration, and the pupils were dilated. The nausea passed off, with the local anæsthesia, in about twenty minutes, leaving some dizziness for an hour or so longer.

The same evening Dr. Halsted removed a small congenital cystic tumor, situated directly over the outer third of the left supra-orbital ridge, and believed to be a meningocele, the communication of which with the cranial cavity had become shut off. Nineteen minims of the four-per-cent. solution were given hypodermically in divided doses, one external to the tumor, and the others close to the supra-orbital notch. In about five minutes the anæsthesia was complete. The incision through the skin and the earlier steps of the operation were not felt at all, but, in consequence of the close adhesions of the sac and its extensive prolongations, especially into the upper lid, the operation was somewhat protracted, and the anæsthesia had passed off to a considerable extent before it was completed. I was informed of a case, occurring on the same day, in which cocaine was injected, preparatory to performing a small plastic operation, in the same region, but no anæsthesia of the field of operation was produced. On inquiry, I was told that the injections had been given *above* the point where the incisions were to be made.

This afternoon, having occasion to have the left first upper incisor tooth filled, and finding that the dentine was extremely sensitive, I induced Dr. Nash, of No. 31 West Thirty-first Street, to try the effects of cocaine. The needle was passed through the mucous membrane of the mouth to a point as close as possible to the infra-orbital foramen, and eight minims were injected. In two minutes there was complete anæsthesia of the left half of the upper lip and of the cheek somewhat beyond the angle of the mouth (as I was in the dentist's chair, I could not determine the exact limits), involving both the cutaneous and the mucous surfaces; also of the left side of the lower border of the septum nasi and of the anterior surface and lower border of the gums, extending from the median line to the first molar tooth. Forcing the teeth apart with a wedge caused no pain except

when the wedge impinged on the unaffected mucous membrane of the posterior surface of the gums. Dr. Nash was then able to scrape out the cavity in the tooth, which had previously been so exquisitely sensitive, and to fill it, without my experiencing any sensation whatever. The anesthesia was complete until twenty-six minutes after the injection, and sensibility was much diminished for ten or fifteen minutes longer. Piercing the mucous membrane with the needle caused pain like the prick of a pin, but its subsequent introduction until it struck the bone and the injection of the solution were not felt. In the same way, the introduction of the needle into the ulnar nerve caused quite severe pain, with tingling down to the little finger, but the injection of the fluid gave rise to no sensation. In the experiment on the teeth, it surprised me that the incisor tooth should be rendered insensitive, as the anterior-superior dental nerve is given off in the infra-orbital canal. I can only suppose that the effect extends some distance along the nerve centrally, or that the fluid traveled along the sheath of the nerve into the canal.

We have already used this mode of administration successfully in a number of cases in the Roosevelt Hospital Out-door Department, and it is obvious that, when the limits of safety have been determined, it may find very wide application. For instance, in addition to the usual application to the conjunctiva, in operations on the eye, an injection into the orbit, in the neighborhood of the ciliary nerves, would doubtless diminish the liability to a very grave accident, which, I understand, has already occurred several times in the city—namely, the extrusion of the lens, from blepharospasm, occurring during iridectomy performed with the aid of cocaine. We have injected twenty minims a number of times, without causing any constitutional symptoms.

Very truly yours,

R. J. HALL, M. D.

Postscript, December 1st.—Since the foregoing was written we have made some additional experiments which seem of interest. Dr. Halsted gave Mr. Locke, a medical student, an injection of nine minims, trying to reach with the point of the needle the inferior dental nerve where it enters the dental canal. In from four to six minutes there was complete anesthesia of the tongue, on the side where the injection had been given, extending to the median line and backward to the base as far as could be reached with a pointed instrument. There was, further, complete anesthesia of the gums, anteriorly and posteriorly, to the median line, and all the teeth on that side were insensitive to blows. The soft palate and the uvula, on the same side, were anæmic and quite insensitive. Mr. Locke thought also that there was some diminution of sensibility in the domain of the auriculo-temporal nerve.

In four or five other cases where the injection was made in the same way, from fifteen to twenty minims being used, the fluid seemed to have come nearer the lingual than the inferior dental. In all, the tongue was affected sooner than the gums; the anesthesia extended as far back as the epiglottis, and the sense of taste was abolished on the affected side; and the posterior surface of the gums was earlier and more completely anesthetized than the anterior.

This evening Dr. Halsted gave me an injection of seventeen minims, the needle being introduced along the internal surface of the left ramus until it touched the inferior dental nerve, causing a sharp twinge along the whole line of the lower teeth. In three minutes there was numbness and tingling of the skin, extending from the angle of the mouth to the median line, and also of the left border of the tongue. In six minutes there was complete anesthesia of the left half of the lower lip, on both the cutaneous and the mucous surfaces, extending from the median line to the angle of the mouth and downward to the inferior

border of the jaw. A pin thrust completely through the lip caused no sensation whatever. There was also complete anesthesia of the posterior surface of the gums and of the lower teeth on the left side, exactly to the median line; hard blows upon the teeth with the back of a knife caused no sensation. The anterior surface of the gums was anæsthetic only from the median line to the first bicuspid. There was a small area of complete anesthesia, about the middle third of the left border of the tongue, not more than an inch in diameter. A slight return of sensation began twenty-five minutes after the injection, and five minutes later no complete anesthesia remained anywhere. I should mention that fifteen to twenty minims in this region caused, in two or three cases, slight constitutional symptoms similar to those previously described.

HYPODERMIC INJECTIONS OF PHENIC ACID IN MALARIAL FEVER.

46 WEST THIRTY-SECOND STREET, November 12, 1884.

To the Editor of the New York Medical Journal:

SIR: Under "Therapeutical Notes," in your last issue (November 8th), you report from "Union médicale" one case of intermittent fever successfully treated by hypodermic injections of phenic acid—1 to 100. Will you allow me to bring to your notice, and that of the readers of your valuable journal, that this method of treatment is by no means new in this country? Ever since 1871 I have cured by that system hundreds of cases where both quinine and arsenic had failed.

I do not claim to be the only one who employs the treatment here. I know that, since 1876 or 1877, Dr. Glover C. Arnold, to whom I then communicated my results with the phenic acid, has from that time given it the preference over all other febrifuges in intermittent fever. No less enthusiastic is Dr. Charles F. Roberts, who, but a few days ago, was telling me of his unvarying success in like cases.

It has been said by some that the injection is liable to cause abscesses. All I can say is, that I never had any, and I doubt the liability if a pure article is made use of. I always use a solution of phenic acid—freed from cresylic acid, rosolic acid, and rosanilin—which has been deoxidized and combined in its nascent state. Furthermore, I will state that I use a two-per-cent. solution, injecting one hundred drops at a time. Within a few weeks, sometimes in less than a week, I obtain a normal temperature, and, what is more, it remains such.

Very respectfully,

GIBBLANT DURANT, M. D.

Proceedings of Societies.

NEW YORK ACADEMY OF MEDICINE.

Meeting of November 20, 1884.

The President, FORDYCE BARKER, M. D., LL. D., in the chair.

A New Syringe for washing out the bladder, abscess-cavities, etc., was shown by Dr. ALFRED C. POST. It was made by the Messrs. Tiemann & Co., of hard rubber, and admitted of ready inspection of the piston from either end.

The President introduced Dr. Wile, of Connecticut, and Dr. Price, of San Francisco, and invited them to seats on the platform.

The Surgical Management of Rhachitic Deformities of the Lower Extremities was the title of the paper of the evening, read by Dr. V. P. GIBNEY. [See pages 606 and 637.]

Dr. J. D. BRYANT agreed with Dr. Gibney that many cases, in children, might safely be left to nature, but it was a question whether that was true of bow-legs. Doubtless, much was to be gained by hygienic treatment. As a rule, if he found the bones springy, he made two or three attempts a week at correction by forcible pressure on the convex side of the limb, and he thought, with Dr. Gibney, that any case in which correction could be thus accomplished was a suitable one for treatment by apparatus. He was inclined to favor a spring to make moderate pressure against the point of greatest convexity. It was his impression that osteoclasia had been but little used in New York, and certainly, in cases where its use would endanger the integrity of the knee, there was sufficient reason for preferring supra-condylar osteotomy. In his opinion, osteotomy, especially if performed with antiseptic precautions, was one of the greatest surgical advances of the century; far from having met with any serious results after either the supra-condylar or the tibial operation, he had not even met with the formation of a drop of pus after them. A patient sixteen years old—the oldest one on whom he had done the supra-condylar operation—had a temperature of 102° F. on the third day, and another slight rise took place afterward, but there seemed to be no local condition at fault, and the patient made a good recovery.

Dr. C. T. POORE called attention to the importance of knowing the exact pathological condition that lay at the bottom of knock-knee, without which knowledge there could be no firm foundation for treatment. In many cases of apparent knock-knee there was really no bony lesion; where there was one, he believed it to be rhachitic, traumatic cases being excluded. In the early stage of rickets, before consolidation had taken place, unquestionably the bones could be bent, but he could not understand how they could be straightened by mechanical means after consolidation had taken place. Dr. Gibney had seen the spontaneous cure of knock-knee of true bony origin (for his word was to be taken without question), but such cases could not be numerous; as for himself, he had not seen any. He thought that knock-knee of rhachitic origin was much more common in New York now than it had been a few years ago, and the fact that so few adults were seen with it was due to the comparative exemption of this country from the disease. All cases could be treated successfully with splints properly applied, if they were taken in time, but he could not see what was to be gained by continuing their use beyond a certain length of time if no benefit had been produced; if the deformity could not be corrected when the bone was soft, certainly it could not after it had become hard. The age at which consolidation took place varied in different children, according to the state of the nutrition. A deformity remaining after it had occurred called for an operation. In most of the cases of osteotomy hemorrhage might have been avoided. He had never kept a patient in bed more than five weeks. As a rule, he removed the plaster-of-Paris in the fourth week, and the patient was out of bed within a few days. He had never known the deformity to return. As to osteoclasia for bow-legs, he thought it far better than manual force, for, if the curvature was far enough away from the malleoli, the fracture could be produced at any desired point. He had never seen any accident from the operation, nor had he seen it fail to correct the deformity. Long curves, he thought, were better treated by osteoclasia, while short, angular curves, near the epiphyses, and anterior curves, were more suitable for osteotomy. He did not employ Listerism, strictly speaking.

Dr. M. H. HENRY said that for many years, at the State Immigrants' Hospital, there had been a great number of children of foreign birth. Only a few Italian children had deformities of the lower limbs. Most of the deformed were rhachitic, and

with better diet, bedding, and clothing, they almost always recovered with little or no surgical treatment.

Dr. M. J. ROBERTS remarked that, in connection with the rarity of bow-legs and knock-knee in the adults of this city, it should not be forgotten that the death-rate was greater among dyscrasic children. Moreover, recovery from these deformities was not generally complete, and he could point out many persons with moderate deformities on the streets. It would be found that they were incapable of prolonged locomotion or of standing for a considerable length of time. He showed photographs illustrating the statement that recovery was not generally complete. He differed with Dr. Gibney as to his statement that in bow-legs the deformity pertained to the entire limb; photographs of the denuded bones showed that their shafts were nearly or quite normal in shape, and that the trouble was at the joint and at the junction of the epiphysis with the diaphysis. Although spontaneous recovery would often occur, nature could be aided in almost every case. The scope of manual force was limited to cases in which the bone was quite soft. Different mechanical appliances had proved of benefit, especially the one devised by Dr. Davis. It was important that instruments of precision should be used in determining the degree of curvature—without such a criterion, the statement of a surgeon that a patient had recovered was not of much value. Dr. Roberts regretted that more had not been said in the paper as to the means of performing osteotomy. There were objections to chisels, but, by means of his circular saw, an awkward operator was not likely to do harm.

The PRESIDENT inquired as to the influence of sex on the frequency of rhachitic deformities of the lower extremities, and also on the occurrence of spontaneous cure. Anxious mothers had often expressed to him their solicitude as to their little girls with bow-legs.

Dr. GIBNEY replied that, so far as he could remember, the statistics of the Hospital for the Ruptured and Crippled showed about the same number of cases in the two sexes. A great many women who had suffered from bow-legs in early childhood would be found to have flat-foot. He thought that a good many of the cases seen in adults in this city were not cases of knock-knee of the kind treated of in his paper, but occurred in stout men, and were of an atonic type, as described by Little.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

AN adjourned annual and a stated meeting, held November 24, 1884.

Address of the Retiring President.—Dr. S. O. VAN DER POEL, the retiring President, read an address in which he referred to the amount and quality of the work done by the society during the past year, and to the large number of new members—one hundred and twenty-seven—since the last annual meeting, and thanked the society for the uniform courtesy which he had received during his term of office.

Address of the President for the Ensuing Year.—Dr. DANIEL LEWIS then called the stated meeting to order, and, after speaking in complimentary terms of the retiring President, and promising to advance the interests of the society as far as lay in his power, referred to the importance of all physicians who wished to take part in framing laws relating to the medical profession in the county and State joining the society, and said that the law of 1880 regulating the practice of medicine in the State of New York had proved more far-reaching and effective than even its framers had anticipated. The necessity for a State Medical Examining Board as a means of suppressing quackery and promoting a higher grade of medical education was obvious. Such a board, however, should it be organized, as it was proba-

ble it would be in the near future, should have power to revoke a license to practice for sufficient grounds. He also thought it might add to the scientific interest of the meetings if the gentlemen expecting to take part in the discussion of any given paper would send their names to the secretary, that the fact might be made known on the cards of announcement. He recommended timely measures against the possibility of an epidemic of cholera. The donation which the College of Physicians and Surgeons had lately received from Mr. Vanderbilt would probably soon lead to a change of location of that college, and he therefore thought it advisable that the society procure, at an early date, another hall in which to hold its meetings.

Standing Committees.—The President then announced the following members of committees for the ensuing year: On Hygiene, Dr. Stephen Smith, Dr. Alexander Hadden, Dr. E. H. Jones, Dr. Cyrus Edson, and Dr. William L. Hardy; on Ethics, Dr. George A. Peters, Dr. W. T. Alexander, Dr. Mark Blumenthal, Dr. C. O. Lee, and Dr. Edward Waitzfelder; on Prize Essays, Dr. F. R. Sturgis, Dr. Frank P. Foster, and Dr. W. R. Birdsall; Auditing Committee, Dr. P. Albert Morrow, and Dr. Gorham Bacon.

On motion of Dr. VAN DER POEL, the matter of obtaining a suitable hall for the society was referred to the Comitia Minora.

On the Third Stage of Labor.—Dr. SIMON BARUCH read a paper with this title, and said that his reason for doing so was that experienced and learned obstetricians were still at variance as to the proper method of conducting the third stage of labor. He then briefly referred to the common division of labor into three stages, the first, second, and third, which he accepted. In general terms it might be said that in proportion as labor advanced was any deviation from the normal processes dangerous to the mother. With the advent of the third stage the patient was ushered into a condition in which the perils from abnormal processes culminated. Here attention to details which in themselves might seem insignificant was all-important.

There were three methods of dealing with the placenta in vogue at present. The first was the ancient method of pure expectancy; the second consisted in active assistance in the removal of the placenta, and had had as outgrowths the Dublin and afterward the Credé methods. The third, or eclectic method, occupied a middle ground between the extremes of expectancy and energy of procedure. The author thought that here, as elsewhere, the golden mean was to be desired. He then quoted the views of various authorities with regard to the value of these several methods, particularly the expectant and Credé's, and showed that many of those who professed to practice Credé's method failed to do so in fact. Reliable statistics of cases treated according to the expectant plan and the method practiced by Credé showed the advantages of the latter.

It probably had happened to every obstetrician to meet with cases in which the placenta had been retained perhaps for two hours without doing any harm, but it seemed unreasonable to maintain that it was of any advantage to have the membranes retained for a length of time. The author had had but a single case in which the placenta had been unduly retained within the uterine cavity. He thought that many lives had been lost by waiting for the uterus to expel the placenta of its own accord after abnormal or protracted labor. Every case should be treated according to its own peculiar features. It could be of no advantage to leave a woman lying hour after hour in her own gore, in anxious suspense and great discomfort, waiting with the idea that we were giving nature fair play for the expulsion of the placenta. The eclectic method sought to make use of all the advantages possessed by Credé's while omitting any which it might be well to discard. The author then referred

to the twofold power of contraction possessed by the uterus, the one being tonic and the other clonic. The latter only constituted a true uterine pain. The former was illustrated during uterine involution after delivery. These clonic spasms for the expulsion of the placenta, or the third stage of labor, might be modified and rendered more or less abnormal by one or more unnatural conditions, such as social surroundings, peculiarities in the second stage, the use of chloroform during labor, and a tendency to hæmorrhage. The author spoke of his experience in midwifery among the colored people of the South as compared with that among the higher classes of the metropolis. In the woman of high social position many hours usually passed in what were called preparatory pains, and by the time the second stage had been reached the nervous system was in a high state of reflex irritability, the expulsive contractions were not so steady and forcible, and here he believed existed a cause of rupture of the perinæum, as during the last four years of his obstetric practice, which had been in the city, he had seen more cases than during his fifteen years' previous practice in the South. In the negroess he often found the placenta expelled into the vagina very soon after the birth of the child, while this was seldom the case in the city woman. In the latter class of cases haste in the third stage of labor was strictly to be avoided; perfect rest under proper surveillance was the true course. Injudicious friction or pressure would cause undue uterine irritability, and fail of the desired object, namely, to obtain strong expulsive contraction. The fact that chloroform had been given indicated that the uterine powers had been reduced; clonic contraction showed that the power of the organ which was necessary for the expulsion of the placenta had been diminished. He would therefore recommend that the use of the anæsthetic be moderated as the third stage was approached, and that Credé's method be aided by the Dublin method of following the uterus down with the hand. When there was a tendency to hæmorrhage Credé's method alone could not be relied upon; the uterus should be followed down as the child receded from its cavity, and should not be permitted to pass from under the hand. The method which he adopted doubtless was that practiced by many other physicians, consisting in gently stroking the uterus to stimulate it to contraction, of grasping it with the outspread fingers, intensifying the strength of the contraction, and making downward pressure for the purpose of aiding in expelling the placenta. It might be necessary, in some cases in which the placenta was grasped by the neck of the uterus, to make traction upon the cord, or to insert the disinfected fingers and make direct traction upon the placenta itself. It was his custom to place the two fingers of the right hand within the vulva while the uterus was being compressed with the left hand, in order to guard against too forcible expulsion and rupture of the membranes. The author regarded twisting of the membranes as objectionable, as it was liable to lead to their being torn.

Dr. WILLIAM M. POLK heartily agreed with the author of the paper in saying that we were not in a position to discard Credé's method. It seemed to him that the method had been so rich in good fruits since its introduction into America, as shown by statistics, that its advantages were placed beyond controversy. He certainly had never seriously contemplated abandoning it in any respect, and he could not understand how any practitioner of experience could say that Credé's method should be given up. There were one or two points, however, in the paper to which he must take amiable exception. For instance, ceasing the administration of chloroform at the close of the second stage, or as the child's head began to distend the perinæum, seemed to him as very improper, as this was just the time when the patient most felt the need of the anæsthetic, and he thought the damage which pressing the chloroform at this moment

might do would be fully compensated for by the relief which it would give. Of course every one knew the danger of producing inertia of the uterus, and this danger had appeared to him to be so great that he had at moments almost contemplated never using the agent again, but when he did employ it he continued its administration until the head was virtually expelled.

He further disagreed with the author with regard to twisting the membranes. He had seen no harm come from the practice, and he thought it might do good. If in five minutes after the birth of the child the uterus did not show a tendency to contract and expel the placenta, he thought it our duty to begin to practice Credé's method, and, if, after the lapse of from half an hour to three quarters of an hour, by this method the membranes were not expelled, he should regard the case as a pathological one.

Dr. BARUCH inquired of Dr. Polk what had been his experience with reference to expulsion of the placenta into the vagina shortly after the second stage of labor among the women of higher social life.

Dr. POLK replied that he had found experience to vary in this matter, depending upon the health and strength of the woman. In weak women the placenta was liable to be retained within the os, while in the stronger, whatever might be their social standing, it would probably be expelled.

Dr. ROBERT A. MURRAY believed, with Dr. Baruch, that no method would take the place of Credé's in cases demanding its use, but he believed also that nearly all the physicians in New York city practiced a method which was superior to Credé's in the large majority of cases of midwifery. It was taught, he believed, by all, or nearly all, professors of midwifery in the city that, after the second stage of labor had been completed, the physician should keep the hand upon the uterus, aiding in its contraction, until the organ had contracted permanently. If this were done, the true expression method of Credé would only be applicable in cases in which hæmorrhage was threatened after the use of chloroform, or after extreme exhaustion of the patient from prolonged or instrumental delivery. He practiced twisting of the membranes.

Dr. J. H. FRUITNIGHT agreed with the author as to the advantage of placing the hand upon the vaginal orifice to guard against too rapid expulsion of the membranes. He considered twisting of the membranes a proper procedure. Out of six hundred and fifty cases of midwifery, he had had retention of the membranes in one case, and post-partum hæmorrhage in three or four. He regarded the placenta as a foreign body, which should be expelled from the cavity of the uterus as soon as practicable.

Dr. LEWIN thought the paper gave one the impression that the Dublin school and English physicians interfered in the third stage of labor more than they did in fact. He spoke from his experience in the hospitals and attendance on societies at which this subject had been discussed. He thought he was not mistaken in his recollection that their practice usually was to adopt the expectant plan; at the same time, however, they would not exclude active assistance, especially in cases which seemed really to call for it. They did not object to removal of the placenta when it lay free in the vagina, and they favored twisting of the membranes, but not pulling upon them.

Dr. MALCOLM McLEAN directed attention to the importance of having a clean vessel at hand into which to cast the placenta, in order that it might be examined carefully, to see whether a portion of it had been left in the uterine cavity.

Dr. BARUCH, in closing the discussion, said, with regard to Dr. Polk's statement concerning the use of chloroform, that he recognized the desirability of lessening the patient's sufferings, which were very intense at the close of the second stage, and for that reason he continued its administration in cases which

demand the employment of the anæsthetic up to a moment before the birth of the child. His only objection to twisting the membranes was that there was a temptation and a liability to make some traction during the procedure, and this would favor tearing.

A Medical Register.—Dr. PIFFARD offered resolutions empowering the Comitia Minora to provide for the printing of a medical register including the names of members of the society. Carried.

CHICAGO GYNÆCOLOGICAL SOCIETY.

Meeting of November 21, 1884.

The President, Dr. H. P. MERRIMAN, in the chair.

[For the notes from which the following report is condensed we are indebted to the society's editor, Dr. W. W. JAGGARD.]

Discussion on Abortion.—Dr. EDWARD WARREN SAWYER, who opened the discussion by appointment, first called attention to the frequency of abortion, but remarked that he thought experience did not bear out Mme. La Chapelle's estimate that it was as frequent as labor at term. In the course of ten years he had seen only between forty and forty-five cases. In his own practice none had been fatal, and he had seen but one fatal case in the practice of others, which case was complicated with cellulitis and pneumonia. Abortions due to natural causes usually terminated favorably, while those that were caused by accidental or intentional violence constituted the *bête noir* of the profession; in the former the ovum and the decidua were commonly expelled entire, but in the latter there was apt to be more or less mutilation. When the embryo was expelled before the membranes, it was frequently lost; moreover, complete absorption of the embryo might take place as late as the fourth week; so that the absence of the fetus was not a positive indication that there had been no abortion.

As to the treatment of abortion, the two distinct courses—the radical method of evacuating the uterus immediately, and the plan of waiting patiently—had each in turn been advocated and opposed. He himself had followed the expectant method; he had waited as long as a week for nature to complete the expulsion of the ovum, and he had never seen any untoward consequences from it. He enjoined absolute rest in the horizontal posture, and gave quinine and alcohol as they were required. Apart from the vaginal tampon, he used no local treatment further than vaginal injections of liquor sodæ chlorinatæ. He objected to the removal of the whole or any part of the product of conception from the uterus, because: (1) it was painful, involved the use of an anæsthetic, and predisposed to hæmorrhage from uterine inertia; (2) an assistant was necessary; (3) the amount of unavoidable injury to the genital tract was considerable.

In conclusion, Dr. Sawyer showed an unusual specimen, consisting of an intact amniotic sac, inclosing a five-months fœtus, with a velamentous insertion of the umbilical cord. A separation having taken place between the amnion and the chorion, the chorion, placenta, and decidua had remained within the uterus. The amniotic sac having been expelled intact, he had paid no further attention to the mass, and had told the patient that nothing more was to be feared, but the next morning he was told that, an hour after his departure, pain and hæmorrhage had come on again, and another mass had been expelled, which proved to be the chorion, placenta, and decidua. His friend, Dr. Albert G. Paine, had seen a case quite similar.

Dr. W. W. JAGGARD said that separation between the amnion and the chorion was relatively infrequent during the sixth and seventh months, but was not uncommon at an earlier period. In regard to the treatment of inevitable abortion, when the ovum

was expelled in an intact or mutilated condition, and the decidua or portions of the fetal membranes remained within the uterine cavity, it was necessary to regard the natural history of the condition, which had been appropriately termed by Breslau "incomplete abortion." Its terminations were, briefly, as follows: 1. Spontaneous elimination of the retained portions, as the result of retrograde metamorphoses, accompanied by intermittent hemorrhages and uterine contractions. 2. Sometimes, although seldom, the hemorrhage ceased entirely and the patient was apparently well, but, after an interval varying from a few days to weeks or months, pain and hemorrhage suddenly came on, and the mass was expelled. This retention, with a long interval of rest, was noticed when the placental or decidual attachments were intact. That this act constituted the termination of the labor, so to speak, was shown by the fact that the secretion of milk was established at this time, and the reductive metamorphosis began. 3. More frequently the retained decidua or placenta underwent suppurative or ichorous changes, and there was danger of systemic infection, in spite of the thrombosis of the uterine sinuses and the proliferative change in the uterine mucosa. 4. The retained mass became converted into placental or fibrinous polypi, always requiring operative interference.

Each of these four terminations involved danger to the mother. Their natural history (for the elucidation of which Spiegelberg was entitled to special recognition) made in favor of the so-called radical treatment, evacuation of the uterus at the earliest possible period. The plan recommended by Dr. Mundé, in the "American Journal of Obstetrics" for February, 1883, was worthy of high commendation. The use of one finger within the uterus and one hand placed over the fundus was preferable to that of instruments when it was equally effective. The subsequent treatment was of extreme importance. Whenever the cavity of the uterus was invaded by the finger, or any instrument, it should be irrigated with some antiseptic solution. Two-per-cent. solutions of carbolic acid, and a one-to-two-thousand solution of bichloride of mercury, were efficient in the destructive conditions that favored decomposition and sepsis. After the irrigation, it was a good plan to insert a crayon of iodoform, weighing not less than six grammes, within the uterus. Symptoms of iodoform poisoning rarely if ever followed the use of this quantity, ten grammes being usually required to produce toxemia.

Dr. PHILIP ADOLPHUS said that abortions were more common among multiparæ than among primiparæ. By way of prevention, he thought, women ought to sleep by themselves at the times that corresponded to their menstrual periods. When abortion was inevitable, the treatment must be symptomatic. To arrest hemorrhage, the cervix should be plugged, not the vagina, and, for obvious reasons, tents of tupelo or of laminaria should be used, not those of sponge. When there was fætor, the uterus should be emptied with either the finger or a curette.

Dr. DANIEL T. NELSON could not be satisfied until the uterus was empty; he had no sympathy with the expectant plan. The manner of emptying the uterus was of importance; if the cervix was dilated or dilatable, the cavity should be cleared out at once with the finger; if it was neither dilated nor dilatable, it should be plugged, in the manner indicated by Dr. Adolphus, with tupelo or laminaria tents. If the cervix was partially dilated or dilatable, and the uterus was fixed, we should give an anæsthetic to relax the spasm, and proceed as in the first instance—he had no fear that ether would predispose to uterine inertia. In dissecting off the placenta, it was advisable to "glove" the finger-tips with the amnion. In the early months, when the ovum was attached near the cornua, it was necessary to bear in mind the possibility of irregular contraction and the

inclusion of a bit of the placenta within one or the other of the cornua—both of them must be thoroughly explored. When he employed intra-uterine irrigation, which was by no means invariably, he used a one-half-per-cent. solution of carbolic acid or a weak solution of ordinary table salt. It should be hot, from 110° to 120° F., and hot water alone, in the absence of the acid or salt, was an effective cleansing agent, and tended to induce uterine contractions. He had had no experience with iodoform, but regarded it as superfluous in all cases.

Dr. WILLIAM E. CLARKE was more in dread of hæmorrhage and sepsis than of injuring the genital tract. He always emptied the uterus at the earliest possible moment.

Dr. T. D. FIRCH did not regard Dr. Sawyer's specimen as showing a rare condition; he had frequently seen a like separation at the same period. He agreed with Dr. Nelson as to treatment; still, when the cervix was not dilated, he was disposed to favor the expectant plan. At the time of abortion the uterus was in a physiological condition; at a later period operative interference was attended with increased risk, as the organ was then in a pathological state. Usually he found the placenta and the membranes detached, within the lower segment of the uterus. He was not in favor of intra-uterine injections; the vaginal douche was sufficient.

Dr. WILLIAM H. BYFORD said that abortions were more frequent in large cities than in the country. When applied to large communities, Mme. La Chapelle's estimate was not exaggerated. In the country, he thought, one abortion to three labors was about the average. Abortion was never a physiological process, although those caused by disease of the ovum were attended with less danger than those resulting from morbid alvine changes. In the former, the circulation was impaired and the embryo perished, and expulsion followed with a minimum of hæmorrhage, pain, and sepsis. When the cause of abortion was external violence or decidual endometritis, the danger in each of the three directions was increased. The condition shown in Dr. Sawyer's specimen was rare at so late a period, but comparatively common during the early months.

In regard to prevention, he had observed two clinical facts in connection with the habit of abortion. When uterine contractions were the prominent symptom, abortion could be arrested in many cases by absolute rest and opium. When hæmorrhage was severe, all attempts at arresting the process were usually futile. This was especially true during the first three months; at a later period, even when hæmorrhage was severe, abortion might be arrested. As to the treatment of inevitable abortion, he had never seen the time when champions of the expectant and of the radical courses of action did not exist. The treatment must be governed by a consideration of the individual case. In any case, the patient must be carefully watched. He had never seen the hæmorrhage of abortion prove immediately fatal; the acute anæmia, however, might induce a condition that would render the woman more susceptible to sepsis or any intercurrent disease. He feared sepsis and metro-peritonitis more than hæmorrhage. He was conservative as to operative interference, and would let Nature do what she could, interfering only in case of her failure. The finger was preferable to any instrument, and it was not necessary to insist upon the removal of the placenta or the membranes with mathematical accuracy; if the placenta was grasped by an irregularly contracted uterus, the free portion might be cut off, and the rest allowed to remain. If two thirds of the placenta were removed, and the uterus was well contracted, the patient was to be considered in a safe condition. In the event of sepsis, the whole intra-uterine mass should be removed.

Dr. JOHN BARTLETT had found abortions as frequent as labors at term. The product of conception was usually ex-

pelled entire. When abortion was inevitable, two conditions were requisite to justify interference: 1. Dilatation of the canal of the cervix to the extent necessary for the passage of two fingers. 2. More or less complete separation of the decidua from the uterine surface. Until these conditions were present, the vagina ought to be tamponed; he was in the habit of employing the kite-tail tampon. He had seen two cases of retention of the placenta—for three months in one and four months in the other—without symptoms. He had adopted Dr. De Laskie Miller's rule of allowing the tampon to remain in the vagina for twenty-four hours, and had frequently continued that treatment for three days. Braun's colpeurynter was a useful tampon, but no tampon was effective when the hemorrhage was not passive and the uterine contractions were severe. It was necessary to diagnosticate abortion from placenta prævia. Placenta prævia implied simply an *error loci* of the ovum; it was included between the ring of Bandl and the external os. He had never seen a case of abortion terminate fatally from hemorrhage.

Dr. A. H. FOSTER had seen one case in which the placenta was retained for four months without causing serious symptoms. He urged the importance of treatment during the puerperium.

Dr. E. C. DUDLEY referred to the danger of cervical laceration and subinvolution in consequence of abortion. The best method of applying the tampon was with Sims's speculum.

Dr. C. W. EARLE took the middle ground in regard to the radical and the expectant methods of treatment; he did not agree with Dr. Mundé.

The PRESIDENT indorsed Dr. Byford's remarks on the etiology, and said he did not like to use ergot, as it caused irregular contraction of the internal os, imprisoning the placenta without favoring its expulsion. He produced uterine contractions by dilating the os, and then followed the expectant plan.

Dr. SAWYER had observed abortion in the lower animals, and had concluded that nature required but little interference. He briefly sketched the expectant treatment that he was in the habit of recommending.

Casts of the Uterus, gravid and non-gravid, were shown by Dr. BARTLETT. They had been made for purposes of class illustration, and were regarded as exceedingly ingenious.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Meeting of November 6, 1884.

The President, Dr. R. A. CLEEMANN, in the chair.

Removal of the Uterine Appendages for Menstrual Epilepsy; Recovery.—Dr. E. E. MONTGOMERY showed specimens and read the history of the case. The patient, seventeen years old, was admitted into the Philadelphia Hospital April 1, 1884. In childhood she had an attack of inflammatory rheumatism, and began to have epileptic seizures in her thirteenth year. They were slight at first, but had recurred every month, increasing in number and violence, so that now she was unconscious for ten days or a fortnight out of each month. Only once had there been a trace of menstrual discharge, and then for a single day only. She was pale, flabby, anæmic, poorly developed, and extremely nervous. The external genitals were but slightly developed and the uterus was small. There was no special tenderness over the pelvis. Iron, tonics, and a generous diet had been employed; the bromides were not well borne. Owing to her youth and the fact that she had not yet menstruated, it was thought best to try to establish menstruation, and to exhaust the antispasmodics, before resorting to operative interference. All remedial measures having failed completely, the ovaries and

tubes were removed on the 13th of September. Her recovery was uninterrupted until the night of the 26th, when she had four epileptic seizures, and there were slighter attacks during the next three nights, but they were shorter, and during the intervals she was perfectly conscious. During the first four days of October she had spells of staring, with momentary unconsciousness, growing less frequent and lighter. A well-marked convulsion occurred on the night of October 14th, and was followed by from one to four convulsions daily until the 29th, but they had not been so severe as before the operation.

Removal of a Parovarian Cyst; Recovery.—Dr. MONTGOMERY related this case also. An English woman, thirty years old, married, had never been pregnant, but had had an enlargement of the abdomen for seven years. Her menstruation had always been regular and never excessive. It now occurred every three weeks, the flow was very slight, and she suffered from severe pain in the lower part of the abdomen and through the hips the week before it came on. She suffered at other times from pain in the feet and legs, and from a sensation of weight. The tumor had been tapped about six times; the fluid was always of a pale straw-color. The largest quantity removed at any one time was forty pounds. Previous to its removal her weight was one hundred and two pounds. The last tapping was done on the 27th of June. She had had four attacks of peritonitis. When she was first seen, two weeks after the last tapping, the abdomen was swollen and tender, and there was distinct fluctuation. Since that time the abdomen had increased considerably in size, being distended throughout by a prominent tumor, almost symmetrical but projecting slightly to the right side. The circumference at the umbilicus was thirty-two inches, the distance from the symphysis to the umbilicus seven inches, and from the symphysis to the ensiform cartilage thirteen inches. There was distinct fluctuation over the whole tumor, and coughing projected the whole mass forward and downward. The patient's general condition was good, and she was quite active. A parovarian cyst having been diagnosticated, it was decided to make an exploratory incision and remove the tumor if possible, or, if the adhesions proved too great to allow of that, to open the sac, stitch it to the integument, and introduce a drainage-tube, so as to secure obliteration of the sac. On the 9th of October an abdominal incision was made, four inches long, and, although there were adhesions throughout, they were for the most part broken up without difficulty, and no ligatures were needed. The intestines were not seen, being concealed by old inflammatory deposits. The right ovary was found enlarged, and was removed. The wound was closed with seven sutures, and a glass drainage-tube was introduced. A thick layer of salicylated cotton was placed over the wound. Suppositories of morphia were used to control pain, which continued to a greater or lesser extent for two weeks, arising partly from inflammatory conditions and partly from collections of gas in the intestines. The abdominal wound discharged freely, three ounces the first day. The drainage-tube was removed four days after the operation, but the discharge of bloody serum, pus, and flaky lymph continued for full two weeks later, when the wound closed entirely and the patient was discharged.

Placental Polypus simulating Malignant Disease of the Uterus.—Dr. B. F. BAER presented the specimens and related the history of the case. A married woman, thirty-five years old, had had two children at term, the last one twelve years ago. Since that she had had several abortions, but otherwise had had good health. Her mother had died, at the age of thirty-eight, of cancer of the uterus. In the early months of the present year the patient first noticed that her menstruation was becoming too frequent, that she had expulsive pains with it, and that there was a fœtid, watery discharge in the intervals. The

loss of blood increased, and she soon began to show signs of failing health in pallor and loss of flesh. She would not allow a physical exploration until the latter part of July, when she had a violent flooding, with great pain. Dr. R. Armstrong, of Lockhaven, Pa., who was her physician, then made an examination, and found the cervix and the os uteri normal, but the body of the uterus enlarged to more than double its natural size, apparently symmetrical and rather softer than usual. The hemorrhage was controlled by means of ergot and rest. Although the grumous, fetid discharge and the uterine tenesmus continued, she did not have another severe attack of metrorrhagia, probably because of her exsanguinated condition and of the fact that she was suffering from septic absorption. Her temperature rose as high as 104° F., and she had distinct rigors. Her abdomen was tympanitic and very tender to the touch. The condition of the uterus led the doctor to introduce two tents into the cervical canal on the 23d of September. They were allowed to remain twenty-four hours, although their presence increased the violence of the symptoms. When they were removed, a rather soft, friable mass could be felt presenting at the internal os. This led to the fear that the disease might prove to be malignant. A severe colliquative diarrhœa now set in, and the patient's strength became so much reduced that nothing could be done except to give remedies to check the diarrhœa and prevent collapse. On the morning of the 25th, through the kindness of Dr. Armstrong, Dr. Baer saw the patient, who then had a temperature of 105°, her pulse being rapid and feeble. Her stomach was irritable, rejecting everything that was taken, and her bowels were still quite relaxed. Her face presented the ashy hue of malignant disease. The outlook was not favorable for an operation requiring dilatation of the cervix sufficiently to remove the diseased tissue which evidently occupied the uterine cavity, but that was the only course to pursue. Ether having been given, the uterus was found retroverted and fixed by adhesion. The cervix was rigid and but slightly patulous. In view of the existence of peritonitis, it was thought best to try to remove the contents of the uterus without any attempt at further dilatation, as it was feared that the adhesions might be ruptured and the inflammatory action increased. The wire loop of an écraseur was passed through the os, and, by careful manipulation, it was fortunately guided over the tumor and up to its attachment. The loop was closed by traction, and thus the pedicle was severed. The tumor was then seized with a volsella and withdrawn. The index-finger could now be passed into the cavity of the uterus. The pedicle was situated on the posterior wall, near the fundus. The tissues at that part were soft and friable, but the remainder of the surface of the uterine cavity appeared to be free from disease. The stump was cauterized with nitric acid, and a two-grain opium suppository was placed in the rectum. Convalescence was rapid and satisfactory.

On section and close examination, the specimen very much resembled placental tissue, and the microscope showed typical placental villi in its structure. It was the "placental polypus" described by C. Braun in 1851, and somewhat resembled the "fibrinous polypus" of Kiwisch, who thought that these polypi might arise from long-persistent hemorrhage, a kind of apoplexy of the womb, a large coagulum forming, the upper part consisting mostly of fibrin and adhering by a stalk to the uterine wall, while the lower part consisted of red, soft coagulum having a coat of firm fibrin. Scanzoni did not admit this view, but contended that these were cases of abortion, and would, therefore, fall under the class of placental polypi (Barnes). Dr. Baer's own experience agreed with that of Scanzoni. These polypi caused profuse metrorrhagia, and sometimes, as in this case, blood-poisoning. The case furnished another strong argu-

ment in favor of the entire removal of the decidua or placenta after abortion. Who could tell how many lives were lost, or in how many cases health was undermined, by a neglect of this procedure? Death would inevitably have occurred in this case if the uterus had not been emptied. The patient might suffer for months or years as a result of neglect. In this instance the fault was with the patient, for she had been properly advised by her physician. It was true that many patients escaped without serious injury, but that did not prove that the principle and practice of immediate removal should not always be considered the safe course, for here was a case where a neglected abortion had apparently passed off safely, but it almost destroyed the patient's life a long time afterward. Malignant disease was properly suspected from the rapid development of such grave symptoms, from the general cachectic appearance, and from the sensation conveyed to the finger when touching the growth *in situ*. But, when it was found that it had a limited point of attachment, and that the uterine cavity was healthy at all other points, this hypothesis was weakened, and the subsequent examination of the mass established its benign character.

Dr. MONTGOMERY remarked that, where dilatation of the uterine canal had already been partly accomplished, the best instrument for continuing the dilatation was Dr. A. H. Smith's mechanical urethral dilator.

Removal of a Hair-pin from the Uterus.—Dr. BAER showed a hair-pin removed from the uterine cavity of a patient sent him by Dr. Pancoast, of Camden, N. J. The woman, believing herself to be pregnant, had tried to produce an abortion by inserting the pin, grasping the points and introducing the blunt end, using a mirror to obtain a view of the parts. The presence of the pin was readily detected with the uterine sound. At first he thought of dilating with tents, but, as the patient was greatly alarmed and very importunate, he used a steel dilator. In the withdrawal of the pin, one of the points became imbedded in the tissue of the cervix, and dissection was required to release it.

Dr. WHARTON SINKLER showed a hair-pin removed from the vagina of a patient who had tried to introduce it into the uterus to produce abortion. She had failed in her purpose, and also in removing it from the vagina. He found its points widely separated, presenting downward, and hooked into the vagina wall. By bringing the points close together, the pin was removed without difficulty. It had been in the vagina for some time.

Dr. MONTGOMERY, when he was a student, had seen a hair pin removed from the vagina that was thickly incrustated with calcareous matter.

Miscellany.

THERAPEUTICAL NOTES.

Cocaine in Laryngology.—Dr. Edmund Jelinek contributes some interesting statements on this subject to the "Wiener med. Blatt." A the result of numerous experiments in Schrötter's clinic, he says that if the hydrochlorate of cocaine, either in powder or in the form of strong solution, is applied to the mucous membrane, a marked diminution of the sensibility of the parts is noticed within a minute and a half. A solution of one part in ten or twenty is recommended, the formula suggested being as follows:

Hydrochlorate of cocaine.....	1 part;
Alcohol.....	2 parts;
Distilled water.....	3 "

In examinations of the nose and larynx, it is sufficient to pencil the anterior and posterior surfaces of the soft palate, the posterior wall of

the pharynx, and the base of the tongue, the process being repeated after the lapse of a minute, if necessary. The local anesthesia continues for about ten minutes. Professor Schrötter speaks in the highest terms of the new remedy. He has produced most gratifying results by its use in cases of acute and tuberculous laryngitis attended with extreme irritation. Both Schrötter and Störk have removed papillomata from the vocal bands after inducing local anesthesia, and testify to the value of the method.

Kéfir.—Zuber has published a long article upon this subject, in a recent number of the "Gazette hebdomadaire de médecine et de chirurgie." He defines kéfir as kunyss made from cows' milk, but says this is not an exact definition, although it indicates the origin of the preparation. He goes on to say that kéfir is "the product of a peculiar fermentation of milk," and is essentially an alcoholic fluid heavily charged with carbonic-acid gas. The ferment, when isolated, is described as a yellowish substance, which tends to form small granular masses. When this is added to milk, fermentation rapidly occurs, carbonic-acid gas being evolved, while the casein is coagulated. Commercial kéfir is prepared by adding to a bottle of milk a teaspoonful of the ferment, and the milk is kept at a temperature of 15° R. for twenty-four hours, being agitated at frequent intervals. At the end of this time it is filtered, transferred to a fresh bottle, which is carefully corked, and again shaken, for twenty-four hours. This process is repeated once more, and at the end of the third day the strong kéfir is formed. A good preparation should foam violently when the cork is removed, should have a creamy consistence and a pleasant acid smell and taste, and should be free from lumps of casein.

The following analyses are given by Tuschinsky, showing the change in cows' milk after it has passed through the fermentation process:

	Cows' Milk.	Kéfir.
Albumins	48·00	38·00
Fats	38·00	20·00
Lactose	9·025
Alcohol	8·00
Water and salts	873·00	904·975
	1000·00	1000·000

The density of milk is 1·028, that of kéfir 1·026. Beginning with two or three glasses daily, the patient should increase the amount until eight glasses are drunk each day. The writer states that the indications for the use of kéfir are the same as for that of kunyss, viz., impaired nutrition, especially such as results from acute affections or digestive troubles. He cautiously adds that, although the most extravagant praise has been bestowed upon this new remedy, more careful observations are necessary "in order to define its precise therapeutic value."

Jaborandi in Urticaria.—The same journal publishes the following formula for urticaria, recommended by M. Guéneau de Mussy:

Powdered jaborandi,	
Extract of guaiacum, each,	2 grains;
Benzoate of lithium	3 "

Make one pill. The patient is to begin with two pills daily, and increase the number to four in the twenty-four hours. Sulphur baths may be used advantageously in connection with the internal treatment.

Caffeine as a Stimulant.—The same journal gives an abstract of an article by M. Huchard, in which the following formula appears:

Caffeine,	
Benzoate of sodium, each,	75 grains;
Distilled water	9 ounces.

Dose, two to five teaspoonfuls daily. Where the remedy is rejected by the stomach, the following mixture is recommended for hypodermic use:

Salicylate of sodium	45 grains;
Caffeine	1 drachm;
Distilled water	45 minims.

The dose is from six to twelve minims. It is especially recommended in adynamic fevers. M. Huchard states that injections of caffeine are less painful than those of ether, that the former drug exerts direct influence over the cardiac contractions, and that it possesses the double advantage of being at once a diuretic and a stimulant. He has

employed it in the aligid stage of cholera, but his observations have not been sufficiently extended to allow him to speak confidently of its value.

Horsford's Acid Phosphate.—Dr. T. D. Crothers, of Hartford, Conn. ("Atlantic Journal of Medicine"), says that on the 1st of October, 1881, he began a series of comparative studies of the effects of this preparation and the phosphoric acid of the United States Pharmacopœia, which he continued until the 1st of April, 1882. They were made in nineteen selected cases of inebriety and opium addiction, the patients resembling each other very closely in natural vigor, degree of degeneration, and disease. The plan pursued was to begin the use of Horsford's preparation about two weeks after the patients' admission, when all the active symptoms had subsided, and continue its use for six weeks; then, after an interval of one week, try the pharmacopœial acid for an equal length of time, in the mean time noting the pulse, weight, and general condition of the patient every day. He reversed the order in other cases. The difference in every case, after excluding all possible complications, was very prominent, consisting of increased nerve-force, improved heart-action, lessened nutrient perversions, and a somewhat remarkable change in the delusions and insomnia present in many cases. The memory and all the mental operations were visibly strengthened—in one case the patient could not write to his wife, or concentrate his mind on any topic, unless he used a small dose of Horsford's preparation; the other acid would not answer, and, although he did not know the difference, it had not the same effect. The author's studies are not yet complete, because they do not cover a large enough field, or patients that have been treated long enough. But he thinks the following facts are already indicated from this limited study: 1. Horsford's acid phosphate is a remedy of great value in inebriety and opium-taking, particularly in building up functional energy and brain-force. 2. It exceeds the pharmacopœial acid in every case where this may be indicated. 3. As a nutritive medicine, so far, it seems unequalled in its power of restoring the building-up forces of the body.

MEDICO-LEGAL NOTES.

By HENRY A. RILEY, Esq.

The Seizure of Dead Bodies for Debt.—One of the curious questions which the old ecclesiastical lawyers discussed with a good deal of vigor was that of property in dead bodies, together with the further question whether they were liable to seizure for the debts of the living person. Some remnants of the discussion have survived in modern times, but the enlightened opinion of the age has been that the debts of a person do not affect in the least the right to proper and decent burial. It was a common opinion until quite recently that the Roman law allowed a dead body to be seized for debt, but no law of the Twelve Tables that has come down to us permits such seizure, although one of the provisions of the Third Table gave to creditors the singular power of cutting into pieces the body of living debtors who, under certain circumstances, refused to pay. (1 Burns, "Ecc. Law," 2586.) One of the commentators (Huber) is clear that the Roman law did not permit a body to be kept from burial, but thinks that one of the laws allowed the creditors to prevent the body from being carried to a distant burial place.

Stopping a funeral procession on the way to the grave, to insist on the payment of a debt, is such a scandalous proceeding that instances of it must be rare. This actually occurred, however, in 1784, when the funeral procession of Sir Bernard Turner had started from London and was proceeding to Hertfordshire. Some of the creditors made a formal arrest of the body, and stopped the journey until the friends entered into an engagement to pay the debts. It does not appear that the right to do this was ever tested, and no doubt the courts would have refused to enforce promises made under such circumstances. The English law, in the writ of *capias ad satisfaciendum*, directs the officer to produce the body of the debtor at a certain place, but this has never been construed to embrace deceased persons, and the reason of the writ is that he may satisfy the plaintiff of his debt. It would certainly be difficult for the deceased to do this, because at the moment of death all his property, real and personal, passes to heirs, next of kin, or executors, and they are the ones who must pay debts.

In Jones vs. Ashburnham (4 East, 465), Lord Ellenborough, com-

menting upon an earlier case (*Quick vs. Copeland*), where a mother was said to have promised to pay a debt of her son's in forbearance of the arrest of the dead body by the plaintiff, says such a course is "contrary to every principle of law and moral feeling. Such an act is revolting to humanity and illegal, and therefore any promise extorted by fear of it could never be valid in law." In 1842 occurred the case of *Reg. vs. Fox* (2 Queen's Bench, 247), where, under the English laws allowing imprisonment for debt, a person had been confined in jail and had died there. The deceased was in debt to the jailer also, and the latter refused to deliver the body to the relatives until his claims had been satisfied. An application was then made for a mandamus ordering the jailer to deliver the remains without delay, and this was granted without hesitation by the judges. In the same year a somewhat similar case occurred (*Reg. vs. Scott*, 2 Queen's Bench, 248), where the jailer, having claims against an imprisoned debtor who had died during confinement, refused to deliver the body to the relatives, and, when an interment became imperative, buried it within the jail limits. The case came before the Grand Jury, and an indictment was found against the jailer, alleging these facts, and stating further, as an aggravation, that he had buried the body "without any rite of Christian burial, or any funeral ceremony or observance, in a place not being consecrated ground or a customary or fit place for burial, to wit, a yard and within the precincts of the jail." On the trial Judge Maule held that the notion of a jailer being authorized to detain a dead body on account of pecuniary claims was a mistake, and that a jailer doing so was guilty of a misconduct for which he was liable to prosecution.

In this country the offense has been a very infrequent one, and but few of the States have any statutes on the subject, but in two of them at least (Massachusetts and Rhode Island) such laws have been passed. Those of Rhode Island are as follows: "The body of a deceased person shall not be liable to be taken for debt or damages on execution, or upon any process whatever, and if any officer shall, under color of an execution or process, seize or take the body of any deceased person for debt or damages, he shall be fined not exceeding five hundred dollars, or be imprisoned not exceeding six months." In Barnstable County, Massachusetts, a criminal case of this sort was once tried before the late Chief Justice Parsons, and the defendants were convicted, but let off with a small fine on the ground that they were ignorant that it was an offense. In this case the corpse was arrested on a civil process for debt on its way to the grave, in the public highway, in the presence of the friends of the deceased and of a procession which attended the funeral. (1 Russell on Crimes, 408.) The question as to whether there are persons who do actually own the dead body, and what kind of ownership it is, is an interesting one, but is not here discussed.

The Liability of Physicians for Irregularities in Certificates of Insanity.—It is exceedingly important that physicians should comply with all the requirements of the law in preparing their certificates of insanity, as these certificates are the basis of the orders of commitment issued by the magistrates. When such certificates are carelessly drawn, there may be a question of the liability of the physician for the irregularity, and, at all events, he places himself in an unpleasant position. In general, however, it may be said that, when the physician acts in good faith, a mistake as to the actual fact of insanity will not give a person a cause of action after the certificate of insanity has been presented to a court and has been there passed upon. In a case reported in an Eastern State, where suit was brought because the certificate was alleged to be false, the Court stated the law to be as follows: "In an action against a physician for falsely certifying, through malice or negligence, to the insanity of a person, who is thereby committed to the insane asylum, and the pleadings raise the issue as to the sanity of such person at the time when the certificate alleged her to be insane, the burden of proof is on the plaintiff in respect to the averment and claim that she was then sane. In such an action the falsehood, and not the insufficiency of the certificate, is the ground of action against the certifying physicians. Without statutory provisions to that effect there can not be a civil action for damages against a physician, based upon the insufficiency of the methods which he pursued in reaching and certifying a correct conclusion. In such an action it is open to the defendants to prove precisely what were the circumstances under which they acted, what inquiry, investigation, and examination they made, and what the

information was on which they proceeded. If such testimony did not go to the extent of a justification in case their certificate should be found to be false on the question of insanity, it was proper evidence to be considered in awarding damages. If physicians who have certified to the insanity of a person have not made the inquiry and examination which the statute requires, or if their evidence and certificate, in any respect of form or substance, is not sufficient to justify a commitment, the municipal officers should not commit, and, if they do it, it is their fault, and not that of the physicians, provided they have stated facts and opinions truly and have acted with due professional skill and care."

Nurses' Claims for Payment in Small-pox Cases.—A case reported in the last volume of the Law Reports of New Hampshire touches on the right of health officers to enforce the removal of patients suffering from contagious diseases to the special hospitals established for such cases, and the legal claim for services rendered under these circumstances. The case was that of several small-pox patients, members of one family, who were removed against their consent, and that of their parents, by the Health Board of the City of Manchester, to a pest-house provided for such diseases. The health officers employed a sister of the sick persons to care for them as a nurse, promising to pay a reasonable compensation. The law authorized the removal of small-pox patients to the pest-house, but did not in terms give the health board the power to bind the city for the payment of attendance by nurses. A bill was presented to the city authorities, and payment was refused, whereupon suit was brought and judgment recovered. On an appeal, the Supreme Court of the State affirmed the judgment and rendered the following interesting opinion on the law governing such cases: "Having power to compel the confinement of infected persons and prevent their communication with others, and having exercised this power, it became their duty to provide for the wants of those confined there. They could not shut them out from communication with their friends and with the world, and deprive them of any means of obtaining assistance, and at the same time lawfully withhold necessary support and care. They could not establish a hospital without ordinary hospital accommodations, and they could not make the hospital a place of involuntary confinement and escape the duty of supplying the reasonable wants of those who by confinement and seclusion were prevented from applying to any one else for relief. They could not furnish relief against the will of those confined, and afterward recover the expense from them or from those liable in law to support them. If the health officers were obliged by law to confine persons infected with dangerous diseases, and it was their duty to nurse and support them, and if they could not recover the reasonable expense from them or their guardians, they would be remediless unless they could charge the expense upon the city. The law does not require the performance of a duty and at the same time withhold the means reasonably necessary to its performance."

Baker Brown's Influence on Gynecology.—"It is not easy," said Sir Spencer Wells, in a recent lecture on "The Revival of Ovariectomy, and its Influence on Modern Surgery" (*"Medical Times and Gazette"*), "to estimate correctly the part played by Baker Brown in the progress of gynecology. In the minds of many, his really great services have been overshadowed by the errors of his later practice. Some who fully acknowledge and admire what he did to popularize the operations for the cure of ruptured perineum and vesico-vaginal fistula, and who now recognize the great success which attended his adoption afterward of John Clay's suggestion of dividing the pedicle of an ovarian tumor by the combined action of strong compression or crushing with the actual cautery, forget, or never knew, that when Brown assisted me in the case which I have just referred to, and in another which I am about to mention, his own early experience of ovariectomy had led him rather to oppose than encourage the repetition of the operation."

The New York Society of German Physicians.—We are requested to publish the following: "In future, no personal notifications of the meetings of the Society of German Physicians will be sent out. The meetings will continue to be held on the fourth Friday of each month, July and August excepted, at the residence of Dr. A. Jacobi, 110 West Thirty-fourth Street. Every German physician of good standing is invited to attend."

ON A PERFECTED METHOD OF
PHOTOGRAPHING THE LARYNX.*

By THOMAS R. FRENCH, M. D.,

LECTURER ON LARYNGOSCOPY AND DISEASES OF THE THROAT AT THE LONG ISLAND COLLEGE HOSPITAL MEDICAL SCHOOL; CONSULTING LARYNGOSCOPIC SURGEON TO ST. MARY'S HOSPITAL, BROOKLYN.

It is now more than two years ago that, with the assistance of Mr. George B. Brainerd, of Brooklyn, I made my first attempt to photograph the larynx of the living subject. The results obtained at that time were far from satisfactory, yet we were sufficiently encouraged to continue our experiments, and, though meeting at times with difficulties which seemed almost insurmountable, these experiments have finally been brought to a successful termination. Our object has been not only to obtain good photographs, but to devise an easy method by which any expert laryngoscopist can photograph the larynxes of his patients in every-day practice. This we have accomplished.

The assistance rendered by Mr. Brainerd has been invaluable. This gentleman, who is an extremely skillful amateur photographer, is a civil engineer by profession, and his interest in this work has been purely of a scientific character. He became interested in these experiments while under my care for the treatment of an acute affection of the larynx, nearly two years and a half ago. Having volunteered his services, he entered into the work with great enthusiasm, which has continued unabated until the present time.

Prior to the beginning of our experiments, though many had tried, all had failed to produce a good photograph of the larynx. Since then Mr. Lennox Browne and Mr. Emil Behnke, of London, have been successful in obtaining some excellent photographs of Mr. Behnke's larynx. In a paper on "Photography of the Larynx and Soft Palate," by Mr. Lennox Browne, read at the annual meeting of the British Medical Association, held in Liverpool, August, 1883, the writer says: "I do not anticipate that photography of the larynx can be extended beyond the boundary of physiology. To expect photographs from life of pathological conditions is plainly unreasonable, since those we have seen could only have been obtained by elaborate and costly machinery, and, above all, from a subject possessed of unusual, indeed, in my experience, of unequalled knowledge of what was our goal, and skill and endurance necessary for its attainment." I make this quotation to show how great were the difficulties which presented themselves to one who had been successful in obtaining some very good photographs of one subject.

Not only have we succeeded in devising a method for photographing the larynxes of those accustomed to the presence of the mirror in the fauces, but, as some of the photographs in Portfolio I will show, of those upon whom the laryngoscopic mirror was used for the first time, and

who were ignorant of the object of the procedure. Allowing that the fauces are moderately tolerant, with the method which I am about to describe there is, as a rule, no greater difficulty in obtaining photographs of pathological than of normal conditions.

Not only can the larynx be photographed, but it can be done with ease and without assistance. Five minutes are enough for the preparation and arrangement of the instruments, and in another five minutes from three to five exposures may be made; so that, after one has become familiar with this method, allowing that the instruments are ready for use, not more than five minutes will be needed to secure a good photograph of the larynx, which can afterward be developed and printed at leisure.

The obstacles encountered in bringing this method to its present state of perfection were both numerous and great. The first difficulty we met was with the camera. The stationary camera was found impracticable, for reasons which must be apparent to all. This difficulty was overcome by devising a small camera which could be held in the hand while the photograph was being taken. The next difficulty which presented itself was the source of illumination. Plain sunlight was not powerful enough; the oxy-hydrogen light did not give good results; the arc electric light used with the reflector was not satisfactory, and direct illumination with a modified "photophore électrique frontale" of Trouvé, of about twenty-candle power, was only strong enough to make a faint impression on the most sensitive plate. This difficulty was surmounted by a device for use with sunlight, which will be described hereafter. It being necessary, in order to obtain sufficiently large pictures for practical purposes, to place the lens of the camera close to the mouth of the subject, another difficulty was encountered in the condensation of the vapor of the breath upon the lens, and so obscuring or blotting out the impression.

This was overcome by placing a diaphragm in front of the lens, which not only prevented the lens from becoming fogged, but also increased its focal depth.

In order to illuminate and expose the entire larynx in the throat mirror, it was found necessary to use a mirror with a slight convex surface, the illumination being sufficiently strong to allow the loss of light occasioned by the dispersion of the rays from the convex mirror.

The minor difficulties encountered were too numerous to mention; suffice it to say that all have been overcome. About fifteen hundred exposures were made before satisfactory results were obtained.

The apparatus for photographing the larynx, which I now take pleasure in presenting to you, consists of (1) an instrument which I shall term a sunlight concentrator; (2) a camera with throat mirror attached; and (3) a perforated forehead reflector. The sunlight concentrator consists of a hollow truncated cone of metal, ten inches long, in the large end of which is a double convex lens five inches in diameter, which has a focal length of thirteen inches. At the outer end of a short movable tube, fitted into the small end of the cone, is a plano-concave lens of $1\frac{1}{2}$ inch

* Read before the Section of Laryngology, International Medical Congress, Copenhagen, August 16, 1884.

diameter, with its plane surface outward; this is placed an inch or so inside of the point of focus of the double convex lens, and in that position intercepts the converging rays and makes them parallel or divergent, according to its distance from the first lens. With this device a powerful light is obtained, and that, too, without material heat. The cone is mounted on a rod by means of a universal joint, the rod being fastened to the frame of a window into which the sun shines.

The camera (Fig. 1) consists of a box $10\frac{1}{2}$ inches long, $1\frac{1}{4}$ inch wide, and $\frac{3}{4}$ of an inch in thickness. The back opens upon hinges, and allows the introduction of the ground glass or plate-holder. The plate-holder is long enough to admit of five pictures being taken. On the front face of the camera a telescopic tube $3\frac{1}{4}$ inches long, when

run out to its full extent, is attached, and at the outer end of this tube the lens is placed. The lens is made up of two achromatic meniscus lenses of one half-inch diameter, and has a focal length for parallel rays of $1\frac{1}{8}$ inch. In the front part of the camera is a narrow compartment in which slides a drop-shutter of hard rubber. The shutter is released by means of a key on the front face of the camera. At the side of the tube holding the lens is a hollow handle of brass, into which the shank of the throat mirror is passed and fixed by a thumb-screw. The shank is attached to the right side of the frame holding the mirror. The object of this is, mainly, to allow of the lens being held opposite any part

FIG. 1.

of the opening of the mouth. I have already stated that the mirrors used are slightly convex, the radii of their spherical surfaces varying from twelve to twenty-four inches, twelve inches radius being as small as can be used without danger of distortion.

The manner in which the apparatus is used in taking photographs of the larynx is as follows:

I have here a sketch (Fig. 2 shows sketch reduced) which will, perhaps, aid you in understanding the description. A concave reflector attached to a head-band is so arranged over the left eye that the beam of sunlight will be received upon it and thrown into the mouth of the subject. It is important that the beam of light should be thrown from the inner side of the reflector, that nearest the nose, for in this way the angle between the reflected beam and

the axis of the lens is reduced to a minimum. As a rule, the tongue must be protruded and held well out between the thumb and forefinger of the subject's right hand, though in exceptional cases the tongue may be allowed to remain in the mouth. The throat mirror with camera attached, held in the right hand of the observer, is now placed in position in the fauces. *The mirror and light should be so adjusted that with the observer's left eye only the central portion and left side of the larynx can be seen, and be seen to be well illuminated.*

On account of the parallax, or displacement of the image, due to the difference in points of view between the eye and lens, some skill is necessary in managing the illumination and camera, so that the parts which it is desired to bring out will be exposed to the lens if not to the eye. The

image as seen by the eye is not exactly the same as that exposed to the lens. Allowance must therefore be made for this fact, the mirror being held in such a position in the fauces that a straight picture will be insured.

If, now, the tongue does not mound up above the level of the lower edge of the lens and the lower edge of the mirror, it may be taken for granted that, when the plate is exposed, the picture received upon it will be nearly the same as that seen with the left eye in the throat mirror. The plate is exposed by pressing upon the key with the index-finger; this releases the shutter, which in falling makes an instantaneous exposure, amounting, perhaps, to one sixth of a second.

Some of the results obtained with the method just described are contained in these portfolios.* The original photographs are of about one third the size of the larynx. Enlargements will be found opposite most of them, though the originals are very clear and distinct. Portfolio 1 contains forty-one photographic pictures of normal and diseased larynges of twenty-four subjects, and three photographs of the posterior nares of one subject.† In the laryngeal photo-

* Two portfolios were exhibited at the meeting at which this paper was read. A few of the photographs contained in Portfolio 1 have been reproduced, by the artotype process, by Mr. Edward Bierstadt, of New York, and will be found in a plate facing this article. The photographs contained in Portfolio 2 have not been reproduced, but they probably will be very soon.

† All of the photographs of the posterior nares show one or the

graphs the positions occupied by the various structures in phonation, inspiration, and expiration are clearly shown. In many of the photographic pictures the rings of the trachea are shown, and in one photograph even the bifurcation of the trachea can be seen. The diseases shown are: chronic catarrhal laryngitis; chronic laryngitis with hypertrophy of the mucous membrane; paralysis of the arytenoid muscle; swelling of the tissues overlying the arytenoid cartilages in laryngeal phthisis; and papillomatous growths in the larynx.

Portfolio 2 contains four series of photographs, showing the positions of the various structures of the larynx in the production of tones in the different classes of voice. Extremely high and extremely low notes are not shown, but all of the registers of the human voice are represented. The first series shows the positions of the various parts in the production of each note in the soprano voice, from C, treble clef, first line below staff, to A, treble clef, first line above staff, while the tongue was in its natural position in the mouth, as well as while it was protruded. The second series shows the positions of the laryngeal structures in each note of the contralto voice, from D, bass clef, third line, to A, treble clef, first line above staff, also while the tongue was not protruded, as well as while it was held out.

In some of the photographs of the third series more or less mucus is to be seen in the chink of the glottis. This is accounted for by the fact that the subject was suffering from a mild attack of acute laryngitis at the time the photographs were taken. As the photographs were obtained at the last moment, the exhibition of this condition could not be well avoided. This series shows the positions of the various structures of the larynx in the production of each other of the pharyngeal orifices of the Eustachian tubes. In the past few weeks the author has succeeded in photographing the membrana tympani.

note of the tenor voice, from C, bass clef, second space, to A, treble clef, second space, while the tongue was held out. The fourth series shows the positions of the structures of the larynx in the production of each note of the bass voice, from E, bass clef, first line below staff, to C, bass clef, first line above staff, while the tongue was protruded.

It would be inappropriate, neither is it my intention, in this paper, to discuss the conditions which exist in the singing voice. I desire, however, to call your attention to several noticeable features to be observed in these photographs. In all of the series it will be seen that the epiglottis is not shown to be gradually raised as the voice ascends the scale.

It is generally conceded that, all other conditions being the same, the higher the note sounded, the higher the epiglottis will rise. The position of the epiglottis is dependent, largely, upon the position of the tongue, and the position of the tongue varies according to the vowel sounded.

While obtaining these photographs, great pains were taken to secure the production of the same sound, the vowel *e* being used in all upper notes, but, as the results prove, in a few instances I was not entirely successful. So you will observe that in some of the low notes in the series the epiglottis is shown to be as high as in notes an octave above. This, I repeat, must be attributed to the fact that the sub-

FIG. 2.

ject was not successful in sounding the same vowel in each note. Had my subjects been practiced beforehand, better results might have been obtained in this particular. There is, however, no doubt about the accuracy of the positions of the vocal bands as represented.

Again, it will be observed that there is very little difference in the positions of the structures of the larynx, whether the tongue was held out or remained in the mouth. In all of the series the vocal bands can be seen to be shorter, wider, and less closely approximated in the lower than in the upper notes, becoming gradually narrower and longer

as the voice ascends the scale. In the lower notes of the soprano voice the chink of the glottis is widest in its posterior part, but becomes linear at about B, treble clef, third line, and continues so throughout the upper portion of the range. In the contralto voice the chink is wider than in the soprano. It will also be observed that throughout the entire range the chink is widest between the posterior vocal processes, the aperture being wider in the lower than in the upper notes. That this aperture is present in other contralto voices is shown by a photograph of another larynx, in the production of a note in the contralto voice, to be found in Portfolio 1.

In the lower notes of the tenor series the chink of the glottis is widest in its posterior part. At about B, bass clef, first space above staff, it becomes linear, and continues so to G, treble clef, first line, in which note, as well as the one above it, the falsetto mechanism may be seen to have begun. In the photograph representing the lowest note of the bass series a triangular aperture exists between the posterior vocal processes. This soon becomes elliptical in shape, and, gradually diminishing, has nearly, though not quite, disappeared in the photograph representing the highest note of the range, C, bass clef, first line above staff.

While these series of photographs of the singing voice must prove of interest, and probably of value, I do not offer them as proving conclusively the positions always occupied in the production of tones in the different classes of voice, for they are of only one individual of each class. Before they can be accepted they must be verified by other series of a similar character, but this, unfortunately, I have omitted to do, not having had sufficient time.

None of the photographs taken in any of our experiments have been retouched, even in the slightest degree.

While satisfactory photographs may, as a rule, be obtained at the first sitting, two sittings are sometimes required. In the first the focus is to be found. In the second, the focus being known, if all the other conditions are fulfilled, we can feel quite certain of obtaining as many good pictures as are desired.

Now let me explain to you the manner in which the focus of any subject is found. The distance from the position occupied by the mirror in the fauces to the vocal bands varies markedly in males and females, and to a less extent in individuals of the same sex. Without going into details as to the manner in which the method of focusing was arrived at, I will only state that, as a matter of fact, with this instrument, with the throat mirror eight inches from the front face of the camera, in men, with the tongue in or out, the lens must occupy a position of from $2\frac{3}{8}$ of an inch to $2\frac{3}{4}$ of an inch from the face of the camera. In women, from $2\frac{3}{8}$ of an inch to $2\frac{3}{4}$ of an inch from the face of the camera. The difference in the focus, whether the tongue is protruded or not, is about $\frac{1}{8}$ of an inch.

These figures being known, in order to find the exact focus, three exposures should be made, varying the position of the lens $\frac{1}{8}$ of an inch within the limits indicated above. By following these directions, one or more pictures of the larynx or trachea, in good focus, can almost invariably be obtained in three exposures.

If, in taking several photographs of the larynx, care be exercised to vary the position of the mirror slightly, pictures may be obtained which, when viewed with the stereoscope, will present an appearance of greater depth of the cavity of the larynx than can be obtained in any other way.

I am confident that the method of photographing the larynx described in this paper is one of practical utility, and must prove of great service in facilitating the study of the functions and diseases of the larynx.

A NEW APPARATUS FOR TRANSFUSION, WITH REMARKS ON THE INTRA-VASCULAR INJECTION OF BLOOD AND OTHER FLUIDS.*

By JOSEPH C. HUTCHISON, M. D., LL. D.,
BROOKLYN.

NOTWITHSTANDING the operation of transfusion of blood has been practiced for more than five hundred years, and many brilliant illustrations of its value in saving human life have been noted, it must be reluctantly admitted that it has not fulfilled its early promise, and is now resorted to much less frequently than formerly. Within a few months, however, the prevalence of cholera abroad, and the expectation that it will soon revisit this country, have invested the subject of transfusion of blood and other fluids with new interest, especially since many reports of success have been recently recorded in Europe and America.

The writer has for a long time believed that transfusion would be more frequently practiced, and take a higher rank as a therapeutic expedient, if the means for performing the operation were simplified, its dangers diminished, and a proper and easily obtainable fluid could be found for the purpose.

The object of this paper is to consider these requirements.

DESCRIPTION OF THE APPARATUS.—The apparatus which I now exhibit consists of a cylindrical glass receiver, graduated into inches, with a capacity of twelve ounces. It may be made larger if desirable. A metal cap, containing a perforated female screw, is attached to its lower end, having a perforated nipple-shaped termination, to which a rubber tube four feet long is connected, in order to convey the liquid from the receiver to the cannula which enters the blood-vessel. The mouth of the receiver is closed by a rubber stopper, which prevents the escape of heat, and is perforated in the center to admit a thermometer, which fits the opening tightly. When not in use, the thermometer is pushed well down into the receiver, to prevent it from being broken in handling. The cannula has a nipple-shaped end, which is to be slipped into the distal end of the rubber tube, and is furnished with a stop-cock.

The receiver is surrounded by a double jacket of India-rubber, the walls of which are separated by a half-inch space for holding hot water. The water is introduced into the jacket through a tube projecting from the top, fitted with a nipple-end stop-cock. An opening at the top of the jacket admits the receiver, and a smaller one at the bottom

* Read before the New York State Medical Association, November 18, 1884.

allows the metal cap to protrude; it has a narrow opening extending two thirds of its length, to allow the operator to see the graduated marks on the receiver, and also a loop on the top for suspending the apparatus when in use.

METHOD OF USING THE APPARATUS.—

Drop the end of the rubber tube, to which the male screw belonging to the lower end of the receiver has been attached, into a vessel of hot water (150° to 200° F.) placed three or four feet above the patient, and attach the other end of the tube to the stop-cock at the top of the jacket, the receiver having been previously put inside the jacket, because it can not be introduced after the jacket has been filled. Now compress the jacket with the hands to expel the air, which will be seen to rise in bubbles through the water; then remove the compression, and, placing the jacket lower than the surface of the water, a siphon is established, which fills it almost immediately. The jacket, when distended, holds ten ounces, and hugs the receiver closely, so that no air can get between them, which would prevent the heat from being imparted to the receiver. This method of filling the jacket is most convenient and rapid, and a larger amount of water can in this way be introduced than by pouring it into the opening at the top. In the box with the apparatus are three or four bottles containing the salts which are to be injected, mixed in due proportion, ready for solution, with the formula on the labels.

The rubber tube is now detached from the stop-cock at the top of the jacket, and is attached to the cannula; and the other end of the tube is connected with the lower end of the receiver. The apparatus is warmed by filling it with hot water, which is allowed to run off before it is filled with the fluid which is to be injected. The receiver is then closed with the rubber stopper carrying the thermometer, and the apparatus is suspended or held, by an assistant, three or four feet above the vein which is to be opened.

The vein is exposed by lifting a fold of skin transversely across it and dividing it with scissors or a bistoury, making the incision about three fourths of an inch long. A probe is carried behind the vein, which is then picked up with forceps and opened, by a V-incision, with a delicate pair of scissors. Before doing this the stop-cock of the cannula

should be opened and a small quantity of fluid allowed to escape, for the purpose of carrying off the bubbles of air which may have adhered to the walls of the tube. The rapidity with which the fluid is introduced can be regulated by the stop-cock in the cannula. After the cannula is introduced it is fixed in position by the finger laid over the opening in the vein; no ligature is necessary to retain it in position.

A vein at the bend of the arm is usually selected for the operation, a bandage having been previously applied above the elbow, as in phlebotomy, to distend the veins; but, when there is difficulty in finding a vein in this locality, a saphena near the outer ankle may be selected, or the fluid may be introduced into the radial artery, as recommended by Hunter, and recently practiced by Halsted. The central end of the artery should be selected.*

A number of appliances have been devised for the purpose of simplifying the operation of transfusion, and for preventing the entrance of air into the blood-vessels; these results can be best obtained by a simple apparatus, constructed on the principle of the one I have exhibited. If the operation is managed with ordinary care it is impossible for air to enter the vein. The special advantage which this apparatus has is the hot-water jacket. It is a convenient expedient for preventing the fluid to be transfused from becoming cooled below the temperature of the blood during the operation. It is important that the injection should not enter the blood below 98.5° F., and there is no objection to a temperature of 105° F. The temperature can be accurately regulated by the thermometer.

TRANSFUSION OF BLOOD.—It was believed until recently that the reviving power of blood resided in the corpuscles, that transfusion, when performed with the serum alone, or with any other fluid, would prove fruitless. Recently, however, Ott and other observers have demonstrated, by repeated experiments on the lower animals, that the corpuscles of transfused blood, pure or defibrinated, are short-lived and rapidly excreted; that the blood corpuscle is not the important element; that the indication is to restore activity to the circulation by restoring the bulk of the vital fluid so as to enable the organs, especially the heart and brain, to perform their functions duly; that, for these and other reasons, blood is not so good as saline solutions for transfusion in acute anæmia. Other objections are the difficulty of obtaining blood at a moment's notice; the danger that minute masses of fibrin, even when defibrinated blood is used, may obstruct the vessels of the brain, lungs, and liver, and cause fatal disorders; the difficulties attending the operation; the liability of the donor to faint and thus arrest the operation, and also to suffer from phlebitis or other serious consequences. These considerations have prevented the operation from being frequently performed, although the indications for it are by no means rare. In the only case in which I have practiced blood transfusion (Aveling's method was used), the donor, a house physician, fainted, the flow of blood was arrested, and the operation suspended; he developed phlegmonous inflammation and

* "Med. Record," January 5, 1884.

septicæmia, and narrowly escaped with his life. During the operation, air entered the vein of the recipient, but no unfavorable symptoms resulted.*

TRANSFUSION OF THE BLOOD OF THE LOWER ANIMALS.—Blood of the inferior animals, whose corpuscles are not larger than those of man, has been, for a long time, used for transfusion when human blood was not available, and several successful cases have been reported. It is said to be free from any special danger to a healthy human life, and the blood to be more easily obtained than that of man. The exact contrary would be nearer the truth, for in cities lambs and calves are much less numerous than men.

Hasse and Ponfick have found, by experiments on the lower animals, that this operation is not infrequently followed by acute nephritis, suppression of urine, hæmaturia, and uræmic symptoms which, when severe, terminate fatally.

Post-mortem examinations showed that "both kidneys are always greatly swollen; large portions of the straight convoluted tubuli are found blocked up by granular and blood-stained casts, a variable number of which may be detected in the scanty and sanguinolent urine." The appearances and the antecedent symptoms lead to the conclusion that transfusion of blood from an animal of a different species will often imperil life, if it does not lead to a fatal issue.

Ponfick also made the interesting observation that blood taken from an animal of the same species was not followed by grave symptoms, but that the globules of the donor rapidly underwent dissolution in the serum of the individual receiving them, whether man or animal.

TRANSFUSION OF MILK.—The intra-venous injection of milk was first suggested by Dr. E. M. Hoader, of Toronto, Canada, in 1850. He employed it in three cases in the collapsed stage of epidemic cholera; one patient died and two recovered. The operation was revived in 1873 by Dr. J. W. Howe, of New York, who injected milk into the veins of seven dogs, and all died promptly.† He concludes that the milk killed them. He also injected two patients, both of whom died. Professor T. G. Thomas thinks that these deaths occurred because the milk was not fresh. Dr. Thomas has reported seven cases of intra-venous injection of milk, with four complete recoveries,‡ and several successful cases have been reported by Dr. Brinton and Dr. Hunter, of Philadelphia.

I have practiced intra-venous injections of milk three times, with one recovery—on one patient twice. This case was one of pernicious anæmia in a laboring man of large physique.

It was the same case, already referred to, in which I attempted immediate transfusion of blood with Aveling's apparatus, but failed on account of syncope of the donor. One week subsequently five ounces of milk, fresh from the cow, were introduced into the median cephalic vein, by means of a funnel and rubber tube. I did not see the pa-

tient again until three weeks after the operation. His appetite had returned, his pulse was quite full and strong, and his lips and face had considerable color. His appearance had so much improved that at first I failed to recognize him. (See "Med. and Surg. Reporter," March 15, 1879.) Three months subsequently he entered the Brooklyn Hospital in the same anæmic condition as before the last operation. Five ounces of milk were again injected into a vein near the ankle, with Colin's apparatus. This operation did not improve his condition, and he died from exhaustion one week afterward.

Notwithstanding the excellent results that have sometimes followed the intra-venous injection of milk, the operation, it is said, is not free from danger; and it is stated by Laborde that, if animals do not die when milk is injected into the veins, it is because only a small quantity has been used, and even such quantities may occasion serious accidents. The "Lancet" (Feb. 2, 1884) contains an editorial on the results of a series of experiments, reported by Dr. Migliopanza in the "Archives italiennes de biologie," in which he injected milk into the veins of dogs. This observer concludes that milk must first be digested to be properly prepared for the blood; if injected as milk, it simply gives up its fat globules and casein to the kidneys, and passes out of the body by the urine. Milk in the blood in notable quantity, before it has undergone the digestive process, is unassimilable and hurtful, producing vomiting, diarrhæa, prostration, and ultimately death. The butyric element of the milk transfused without previous digestion produces fatty infiltration of the kidneys and chyluria. The sudden introduction of large quantities of milk into the circulation produces great diminution of blood-pressure, due to the collapse of the force of the cardiac systole, and, unless the milk is filtered, to prevent corpuscles larger than those of the blood from entering, obstruction may occur in the pulmonary and cerebral circulation. Albertoni has proposed the injection of the serum of milk, and has actually injected from ninety to one hundred grammes into the veins of dogs without observing any ill effects. Casein introduced into the blood, after being digested, is transformed into urea rather than into food for the tissues.

From all this it is concluded that the fat and casein of milk transfused into the blood before being digested represent an unassimilable material which is discharged from the organism.

SALINE INJECTIONS INTO THE VEINS.—The intra-venous injection of saline solutions was extensively practiced during the cholera epidemic of 1832-'33. More recently this matter has received considerable attention, especially by the Germans; and they have proved, by numerous experiments on animals bled to syncope, that life can be restored by injecting saline solutions into their veins, and that they are even to be preferred to blood for that purpose. Ott injected dogs with pure and defibrinated blood, blood serum, and saline solutions, and found "that the danger from loss of blood, even to two thirds of its whole volume, lies in the disturbed relationship between the caliber of the vessels and the quantity of blood contained therein, not in the dimin-

* Reported in the "Med. and Surg. Reporter," March 15, 1879, by A. T. Bristow, M. D.

† "Med. Record," vol. xiv, p. 443.

‡ "New York Med. Journal," May, 1878.

ished number of red blood corpuscles; and that this danger concerns the volume of the injected fluids also, it being a matter of indifference whether they be albuminous or contain blood corpuscles or not, so long as they are not directly injurious." He proves, further, that the hydræmia arising from saline solutions, though greater than that from blood-transfusion, persists for a shorter time; and that the regeneration of the blood corpuscles, after transfusion of blood, requires more than double the time required after the saline injection. The soluble or corpuscular elements that may be introduced into the vascular system undergo disintegration and excretion, and, since those processes go on more slowly with all other fluids than with the salt solution, it follows that the *restitutio in integrum*, after the injection of the salt solution, takes place more quickly than after transfusion of blood. Since, moreover, there is no danger of the introduction of fibrin-ferment, and the solution is easily prepared, and the technique of the operation very simple, he recommends it in place of transfusion of blood in the human subject, in whom so great a loss of blood as two thirds of its quantity is hardly to be observed.*

Schwarz has also proved, by a series of saline injections into the veins of animals bled to syncope, that the useful element in transfusion is not the blood corpuscle, which is short-lived and rapidly excreted, but the re-establishment of vascular tension and the resulting energetic contractions of the heart. His observations led him to the conclusion that injections of saline solutions were preferable to blood-transfusion in acute anæmia. Schwarz's solution consists of chloride of sodium, 3 jss.; liq. sodæ, gtt. ij.; distilled water, $\frac{3}{4}$ xxxij, warmed to 100° to 104° F.

Jennings, in his recent essay ("On Transfusion," London, 1883), says: "The explanation of the success usually consequent on the intra-venous injection of fluid lies in this, that it is the *dynamic*, rather than the nutritive, value of transfusion which is serviceable in the class of cases under consideration; and, under conditions which have been indicated, and which embrace *most* of the instances where transfusion is called for, I unhesitatingly advise the intra-venous injection of fluid as being certain in its action, comparatively free from danger, and not requiring any special skill, if carried out in accordance with the directions which have been given. If, however, a few ounces of human blood can be safely and readily obtained (*which is exceptional*), it is obvious that the nutritive *quality* of the saline injection will be much enhanced by the admixture of the blood with it, particularly if that blood can be transfused by an immediate method; but this advantage is *generally* a secondary consideration, and it is only in some *rare* cases, such as carbolic-acid poisoning and some of the varieties of chronic anæmia, where, if transfusion be indicated, the transfusion of blood is indispensable." Jennings's solution consists of chloride of sodium, 50 grs.; chloride of potassium, 3 grs.; sulphate of sodium, 2½ grs.; carbonate of sodium, 2½ grs.; phosphate of sodium (Na_2PO_4), 2 grs., dissolved in 20 ounces of water at 100° F., with the addition of 2 drachms

of absolute alcohol, to be injected by means of a siphon of rubber tubing.

Dr. W. T. Bull, of New York, in an important paper (*l. c.*), has tabulated nineteen cases reported within three years, giving the essential details, in which intra-venous injections of salt solutions were used; thirteen were cases of acute anæmia, three were cases of collapse from illuminating gas, and one of collapse from iodoform poisoning.

Quite recently, Professor Mikulicz, of Cracow, in the case of a young man whose life was imperiled by loss of blood from a wound of the brachial artery, injected into the median basilic vein twenty ounces of a saline solution composed of one part of carbonate of sodium, six parts of common salt, and one thousand parts of distilled or twice-boiled water, warmed in a bottle to the temperature of 104°. Dr. Fux, of Laibach, also records the case of a youth who was profoundly anæmic in consequence of repeated hæmorrhages from a wound in the hand, but was prepared for successful operation upon the injured member by an intra-venous injection of eight ounces and a half of a salt solution. I have not had the opportunity of reading the original reports of these cases, but they are given on the high authority of the Philadelphia "Medical News" for September 20, 1884.

My personal experience with saline injections is limited to its use in five cases of epidemic cholera in 1854. The good effects were temporary, but it should be stated that all these cases had been for some time in extreme collapse, moribund indeed, so that the value of the treatment was not fairly tested. I was, however, convinced that a treatment which produced such marvelous temporary effects—such as arousing the patient from profound lethargy, restoring the activity of the circulation as well as warmth and color to the skin, and re-establishing intelligence and speech—would yet prove of great value in such cases, and in cases of acute anæmia from hæmorrhage.

There are many nice points connected with the operation which can only be settled by experiment, such as the best method of introducing the liquid, the proper composition, temperature, specific gravity, quantity, and the rapidity with which it should be introduced. In two cases I injected a fluid composed of common salt, 3 iij, and alcohol, 3 j, in one pint of water, of which two pints were introduced into the median basilic vein, at a temperature varying from 100° to 110° F., and repeated the operation when the algid symptoms reappeared. The following solution, recommended by Dr. Gull in the "Reports on Epidemic Cholera to the Royal College of Physicians," London, 1854, was used in three cases:

Chloride of sodium.....	60 parts by weight;
Chloride of potassium.....	6 " " "
Phosphate of sodium.....	3 " " "
Carbonate of sodium.....	2-13 " " "

"By dissolving one hundred and forty grains of this salt in forty ounces of distilled water, and filtering, we obtain a fluid having a decidedly saline taste, a faintly acid reaction, and nearly approximative in its composition to the fluid effused, minus the organic substances. These are small in amount, and their loss has apparently no important influence on the constitution of the blood."

* Hacker, "Wiener med. Wochenschrift," 1883, No. 37; quoted by Bull, "Med Record," January 5, 1884.

To introduce the fluid into the veins, I used a glass funnel connected with a glass tube three feet long, to which a cannula was attached, raised three feet above the patient's arm.

Dr. Gull's formula is, based upon data by Carl Schmidt of the analysis of healthy blood, as follows:

Soluble Salts in 1,000 Parts of the Water of the Liquor Sanguinis in Health.

Chloride of sodium.....	5.72;
Chloride of potassium.....	.627;
Phosphate of sodium.....	.367;
Sulphate of sodium.....	.176;
Carbonate of sodium.....	2.13 = 9.02.

In Dr. Gull's formula the sulphate of sodium is strangely omitted. A more accurate formula (the one which I recommend), deduced from Schmidt's analysis, is the following:

Chloride of sodium.....	60 grains;
Chloride of potassium.....	6 "
Phosphate of sodium.....	3 "
Sulphate of sodium.....	1.5 "
Carbonate of sodium.....	20 "

Dissolve one powder in 24 ounces of water at 100.5° F. The fluid should enter the vein at a rate not exceeding one ounce per minute, and this can be accurately regulated by means of the stop-cock in the cannula. The quantity of fluid to be injected, if a saline solution is used, is from 12 to 24 ounces. The injection may be stopped when the pulse becomes stronger and the temperature of the peripheral parts of the body more normal.

The arterial injection of fluids has, within a few years, been strongly advocated by Heuter and others, and Halsted, of New York, has reported three successful cases, and favors central arterial transfusion in all cases where the operation is indicated.* The advantages claimed for arterial over venous injections are: (1) air or small clots, accidentally introduced into the blood, are caught and retained in the capillaries and do no harm; (2) there is less danger of overpowering the heart by a too rapid introduction of the fluid; and (3) it is often easier to find an artery, the radial, than a suitable vein; this advantage at least must be conceded.

CASES IN WHICH TRANSFUSION IS INDICATED.—This includes all cases of acute anæmia produced by sudden and copious loss of blood in which life is imperiled; a favorable result may be expected in such cases in a person previously healthy. It is a classical operation, so to speak, in *puerperal hæmorrhage* occurring during or after delivery, and should be practiced not merely to prevent immediate death, but also to avert the danger of blood-poisoning which so often follows the copious loss of blood.

In *hæmorrhage from large vessels*, as well as in *wounds of small vessels*, where the hæmorrhage is only moderate and yet is sufficient to prevent the reaction requisite to enable the surgeon to perform a necessary operation, it is a valuable expedient.

In *hæmorrhage from the bowels and stomach* it is contra-indicated, except as a *dernier ressort*, because of the danger of exciting another hæmorrhage by dislodgment of a throm-

bus; but it may be used in such cases, for the anæmia which follows, several days after the hæmorrhage has ceased.

In *hæmophilia* there is danger of aggravating the hæmorrhage by increasing the force of the heart's action, and there is danger, also, of fresh hæmorrhage from the wound inflicted in the operation. It may be used, however, as a last resource to save life, and Lane has reported such a case, with recovery, in the "Lancet," vol. xvii, p. 185. In *purpura hæmorrhagica* it does not promise much, since it can not lessen the danger of new hæmorrhages.

In *excessive and persistent vomiting*, threatening life, whether produced by the use of ether as an anæsthetic, or by other causes, it may prove of great value. In *epidemic cholera* it should be more generally used, as well as in *acute diarrhæa and dysentery*, and some of the *low forms of fever*, threatening speedy dissolution. It may often be employed with advantage in *chronic surgical anæmia* produced by long-continued suppuration and loss of reparative power. The patient may be brought by transfusion to a favorable condition for operation followed by recovery. Such a case is reported by Barwell in the "Lancet," April 21, 1877. Halsted has reported ("New York Med. Jour.," December 8, 1883) a case of *septicæmia* from suppurative disease of the ankle and tarsal bones in which depletory transfusion was practiced, which so improved the patient as to permit amputation of the leg, with recovery. In *opium-poisoning* transfusion may produce favorable results, especially if depletory withdrawal of blood from one vein was taking place simultaneously with the injection of a proper fluid into another vein. The poison would be eliminated, and the fluid remaining in the body would be more diluted, and therefore contain a less injurious solution of morphine. In the collapse from illuminating-gas poisoning it has recently proved efficient in the hands of Garrigues, Bull, and Halsted, of New York. In such cases, also, depletory transfusion should be practiced. The operation can not be considered dangerous or reckless, for it has often been successfully performed, and followed by recovery, under the most adverse circumstances. It should not be resorted to as a last and desperate remedy. If it is delayed until the patient is moribund, the functions of the venous and circulatory systems may be so far impaired that recovery is impossible, and a temporary improvement is almost certainly followed by a speedy and fatal relapse. It is contra-indicated when there is organic disease of the circulatory organs (Quain).

The matter presented in the preceding pages seems to the writer to justify the following conclusions:

1. It appears to be proved, by experiments upon animals and by clinical facts, that corpuscles of transfused blood are short-lived and rapidly excreted; that the reviving power of blood does not reside in the red corpuscles, and hence the danger of excessive loss of blood is not due to the diminution of its corpuscles and other solid constituents.

2. The important element in transfusion is the restoration of the vital fluid to the vascular system, increasing vascular tension, and causing energetic contractions of the heart.

3. The intra-venous injection of salt solutions in appropriate cases is a more simple and a safer operation than

* "New York Med. Jour.," December 8, 1883.

transfusion of blood. It can be done without the aid of a skilled assistant, and the materials for injection are easily obtained.

4. If further experience should confirm the favorable results from intra-venous injections that have been recently reported at home and abroad, the operation deserves to be held in the highest esteem, and is destined to occupy an important position among therapeutic agents.

DESTRUCTIVE ADENOMA OF THE PETROUS PORTION OF THE TEMPORAL BONE, INVOLVING THE ORGAN OF HEARING.

By SAMUEL SEXTON, M. D.,

AURAL SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

THE patient, G. W. R., a native of New York, was forty-three years of age when he first came to the New York Ear Dispensary for treatment.

The more interesting points in his history were as follows: At the age of ten, he alleges, he was subject to Saint Vitus's dance. From the age of fourteen to twenty-four he was a sailor, and frequently received blows upon the head, but none of surgical importance are remembered. He was, however, during this period of time, subject to dizzy spells, and sometimes received falls, even falling overboard. When twenty-five years old he was married, and afterward engaged in labor on shore. His wife states that during the year previous to their marriage his health seemed to be perfectly good, but that two weeks after this event he suddenly became ill with some head trouble, and coincidentally it was noticed that *when he laughed the face was drawn to the left side, his speech was imperfect, and deglutition gave rise to strangling*—symptoms from which he never afterward recovered.

During the next two years, the particulars of the case not being remembered by the patient nor by his wife, some abatement took place in the symptoms, but at the end of this period another attack occurred, accompanied by vertigo and followed by marked exhaustion. The patient had a severe cold in the head at this time, which gave rise to *deafness and tinnitus aurium in the right ear*, which became permanent.

During the two succeeding years (1860-'61) vertiginous attacks similar to the foregoing occurred frequently, and increased in severity; they were characterized by dizziness, pallor, coldness of the body, and profuse sweating. There was stupor, and unconsciousness even, lasting for an hour, more or less, followed by prostration, dizziness, and intellectual confusion; these were often brought on by over-exertion or excitement. The "heaviness in the head" which had long been experienced now increased; there was much mental depression and nervousness; he "could not work half of the time." Deafness of the right ear was marked. The general condition was very bad. He was treated for "a rush of blood to the head."

The next four years (1862 to 1865) the state of the patient's health varied; at times he could work, but toward the end of this period he began to break down more decidedly; he would come home after driving a trip on the horse-railroad, where he was employed, completely exhausted, and go to bed and sleep three or four hours, and then, after eating a hearty meal, "feel refreshed for the rest of the day."

In 1866 another intercurrent catarrhal inflammation of the middle ear occurred along with *severe pains* in the right ear, interrupting rest and causing much exhaustion. A discharge followed this attack, as on previous occasions, and continued off

and on for a time. The local employment of laudanum and sweet oil was recommended by a physician for the relief of these symptoms. A *severe cough* now began, from which he never afterward recovered, and the pains in the head became constant; he could not sit up without experiencing vertigo, in standing or attempting to walk he was obliged to hold on to some object for support, and on one occasion he fell down in the street and became unconscious.

The history for 1867 to 1869 is wanting, but in 1870 another intercurrent attack of catarrhal inflammation of the middle ear occurred, lasting this time for ten days, and succeeded by vertiginous phenomena.

In the summer of 1871 a free discharge having an offensive odor was established, and he was *laid up for three weeks with a large "gathering on the back of the neck"* (probably in the mastoid region).

In the beginning of 1872 he felt much better again, the improvement in general health continuing during the year; he seldom referred to the head trouble; there was an increase in weight, and his disposition became more cheerful. He would, however, *fall asleep very quickly whenever he sat down*. He managed to attend to light employment now by sleeping for a short time daily. He thinks his vision was now failing.

In April, 1873, severe pains in the head were again experienced, and dry cups were applied for a pain in the side. In June he was taken down with some pulmonary trouble, the cough became very severe, and for a week muco-purulent matter was expectorated, the odor of which was unbearable. He got up from this attack in a few weeks, but the head symptoms became worse, and, mental depression increasing, *he took to drink*. Even in this state he worked some until mid-winter, but his interest in everything was rapidly lessening, a state of inertness and constant drowsiness ensued, and he often expressed a desire to die. Vision continuing to fail, spectacles were used.

In July, 1874, there was another rally, and he found employment as a horse-car driver until February, 1875, when he contracted a severe cold, and had earache for several days, followed by a free discharge from the right ear. The head symptoms became extremely severe, and from this period no further attempt to work was made. He then came to the dispensary.

Present State (May 5, 1875).—Patient is a man of medium stature, a brunette, and weighs one hundred and thirty pounds; states that his nutrition always has been good, notwithstanding the sympathetic nausea frequently experienced. Denies syphilis. Always sleeps on the affected side. He is troubled much by the cough, which is increased on introducing a speculum into the right ear, and *probing the affected ear gives rise to severe paroxysms of coughing*. He is exceedingly nervous, and has twitchings about the face. Is somnolent for days at a time, strengthless, and loses his balance in walking. *He can not swallow food without taking a mouthful of water*.

Paralysis of the right side of the face is marked, and he states that there is a weakening of the right side of the body. The right eye suffers from the exposure due to paralysis. There are constant pains in the head, and altogether he is greatly broken down.

The Ears.—The left ear never gave him any trouble, and its hearing power is very good.

There seems to be almost complete deafness in the right ear, although he fancies that some sounds are still audible.

The external auditory canals are enormous in caliber.

The inner (osseous) portion of the right canal is nearly occluded by the bulging out of its integumentary lining of the posterior-superior wall. This accumulated mass is purplish in appearance, and does not bleed like a polypoid growth when much probed; there is free bleeding, however, on scarification.

There is not a constant discharge from the middle ear, and as the membrana tympani can be seen to be present, but quite dull and parchment-like in appearance, *it is probable that its secretions escape into the mastoid, and thence find an outlet through the posterior wall of the canal, which is much broken down.*

Above and behind the auricle, just beneath the squamoparietal suture, of the size of a twenty-five-cent piece, is a soft, fluctuating tumor, slightly elevating the scalp, without much discoloration, and not tender to the touch. On passing an exploring-needle, some bloody serum was evacuated, leaving the tumor slightly collapsed. So extensive a tumor, situated rather above the region of the pneumatic cells of the mastoid, was puzzling, especially when the nervous phenomena were considered in connection with the history of occasional middle-ear inflammation, and it was, therefore, hoped that an examination of the deeper portions of the tumor might throw further light on the subject of inquiry. A free incision into the tumor was therefore made, evacuating about an ounce more of sero-sanguinolent fluid.

The collapsing walls being separated, it was found that beneath, and extending somewhat deeply, was a mass of friable structure, a portion having the hard, rough feel of bone. Deep pulsation was now felt, which accounted for the impulsion noted in the escaping fluid. The feeling of fullness in the head was very much relieved by the operation. The existence of a considerable intracranial tumor was diagnosed, and, from the tendency to bleed, which was manifested on deep probing into the tumor, it was thought advisable to avoid other surgical procedures than were necessary to secure free drainage for any secretions from the middle ear and mastoid, or from the tumor itself, and await events. Dr. R. H. Derby examined the eyes and

reported: "R. Hm. $\frac{20}{xx}$, V. = $\frac{20}{xx}$; L. Hm. $\frac{20}{xx}$, V. = $\frac{20}{xx}$. The inner half of each disc is whiter than the outer (physiological?); otherwise nothing abnormal about the nerve."

After the operation, the tumor frequently closed up, and the distension caused much pain. In the winter of 1875-'76 the patient was in a wretched state indeed, suffering greatly. He "lost his balance," and could scarcely perform locomotion. The pains in the head were "bursting," and he had a "bound feeling" in the frontal region. The condition of the right eye was worse.

The patient was now obliged to seek in-door relief, which could not be afforded by the Ear Dispensary, and he was admitted to St. Luke's Hospital, April 13, 1876. The records of this hospital show that the case was entered on the register as one of "Aural Polypi; Mastoid Disease."

Dr. George A. Peters, of the surgical staff, proposed to relieve the patient by an operation, and on May 5th, after the projecting integument found in the external auditory canal had been torn away by forceps, an incision was made into the tumor. No pus was evacuated, only serum tinged with blood, but a profuse oozing of blood followed, for the arrest of which compresses were for several days employed. The wound soon afterward healed by granulation. The patient remained in the hospital until June 26th, but *during the remainder of the summer the ear bled quite freely about every two weeks, requiring the use of a basin to catch the blood; in consequence of this, however, the tumor was no longer distended, and he was more comfortable.* On September 5th he again reported at the Ear Dispensary. There was now a red, puffy, vertical cicatrix, an inch and three quarters long, over the seat of the tumor, beneath which the edges of a perforation in the bone were felt. There was a free and offensive discharge from the external auditory canal. He slept much of the time, and had a good appetite. *The right leg was almost useless, its temperature lowered below*

the knee. In October a *large abscess formed over the apex of the mastoid* below the cicatrix; he was weaker, and, in attempting to walk, staggered and fell backward. In consequence of closure of the abscess, he was much of the time very stolid. Had an attack of vomiting which continued all day. *The right hand was very cold.* Pulse 60, weak.

The patient grew worse in November. Slept only when propped up, although continual drowsiness exists. The urine is high-colored; test shows a little albumin, but no casts or sugar. Pulse 80. Heart's action impulsive. Feet and legs swollen and cold. Failure of all the functions increased, the breath was offensive, vomiting frequent, without nausea; constipation was protracted, and was succeeded by diarrhœa with offensive smell. There were rapid loss of vision, much cough, and offensive sputa. Through December he continued to decline; was comatose. There was a free discharge of bloody fluid from the ear, and of purulent matter from the mastoid process; *almost total blindness existed, and there was difficulty in passing urine.*

In the spring of 1877 he rallied a little, but was soon worse than ever; in attempting to stand up would fall to the right; ascites came on, and he could obtain no rest without the use of an opiate. An examination of the eyes was made on April 13th by Dr. Derby, who "found him entirely blind in each eye. Pupils moderately dilated. With ophthalmoscope the retinal vessels, notably the arteries, much reduced in caliber. The optic papillæ did not present an entirely normal appearance; they were paler than in a state of health; they were not, however, a picture of atrophy, nor were there any signs of previous optic neuritis." The want of facilities prevented an exhaustive examination being made.

Death, which was very slow and easy, took place on May 21, 1877, the patient retaining his intellectual faculties to the last.

Post-mortem Examination.—On May 22d an autopsy was made by Dr. Robert Abbe, and there were present Dr. George Baxter Pomeroy, Dr. R. H. Derby, Dr. K. Reid, and the writer.

The meninges were found considerably congested, but there was no evidence of recent inflammation. The growth had pressed

FIG. 1.—THE TUMOR *in situ*: 1, the styloid process; 2, site of the posterior condylar foramen; 3, 4, the dura mater, the edges of which have been detached; 5, 6, the tumor; 7, site of the apex of the petrous bone.

upon the cerebellum so as to make quite a hollow in that part. The meninges over the tumor were slightly adherent to the dura mater covering the growth by old plastic lymph, but readi-

ly stripped up, leaving the tumor clean. No pus was anywhere found within the skull.

A careful examination of the tumor, soon after removal, was made, the specimen having been removed from the cadaver with the contiguous bones of the skull. It occupied, externally, the anterior half of squamous plate of the temporal bone, extending forward to the articulation of the great wing of the sphenoid; anteriorly and inferiorly to the posterior wall of the meatus externus; superiorly to the level of the posterior-superior angle of the great wing of the sphenoid; posteriorly to a vertical line about one inch behind the apex of the mastoid process; downward into the mastoid process. In the space thus included the osseous tissue had been completely eroded, the external mass of the tumor being exposed. Internal to and behind the mastoid portion the osseous tissue had also been eroded to a point at the base of the styloid process, and backward to the line of the occipito-temporal articulation. The internal aspect of the specimen presented a tumor occupying the anterior surface of the petrous portion of the temporal bone, also the entire posterior surface of the same; it was covered by dura mater. The two surfaces were bulged out to the size of a turkey's egg. At the edges of the opening through the squamous plate the dura was very adherent. The whole of the petrous portion of the temporal bone was involved in the tumor, the apex alone remaining, at the orifice of which the trunk of the internal carotid presented, the same extending backward, losing itself in the tumor. A cyst-like portion of the capsule extended down behind the base of petrous portion of the temporal bone, and had the capacity of a pecan-nut.

The largest lobe of the tumor occupied the posterior surface of the petrous bone its whole length. The lesser portion of the tumor occupied the outer three fourths of the anterior surface of the bone. The center of the tumor involved the petrous portion, which it had eroded, so that the osseous walls cracked under pressure. On removing the tumor from its bed, it brought away the whole petrous bone from behind the tympanum inward to within half an inch of the apex.

The membrana tympani was found intact, with the malleus at-

FIG. 2.—A, a portion of the occipital bone; 4, the basilar process; B, a portion of the parietal bone; C, a portion of the squamous part of the temporal bone; 1, site of the external auditory canal (the malleus is seen held in view across the tympanum by shreds of the membrana tympani); 2, the glenoid fossa; 3, the styloid process, which is unusually large in the specimen. The parts about the external auditory canal are much more broken down in the specimen than is shown in the cut.

tached, and both the inner and the middle ear were filled with tumor-tissue. Fig. 2 is an external view of the osseous portion

removed from the skull, after maceration and restoration; the tumor and broken petrous and mastoid portions have been removed. Shreds of the membrana tympani and malleus remained *in situ* even after the specimen was bleached.

The specimen, which had been preserved in alcohol and glycerin since the autopsy, and which had been somewhat mutilated by the removal of a large piece of the tumor, was examined, in August, 1884, by Professor W. H. Welch, M. D., whose interesting report, with illustrative drawing, is subjoined:

"The specimen consists of a part of the petrous portion of the temporal bone, with the adjacent dura mater. These structures are mostly occupied by a tumor. Upon the specimen sent to me evidently only a part of the tumor is present, a considerable portion having been cut away. The tumor now measures $5\frac{1}{2}$ ctm. laterally, 5 ctm. antero-posteriorly, and 4 ctm. in thickness.

"The greater part of the petrous portion of the temporal bone has been destroyed by the tumor, and is now represented only by fragments and spicules of bone in the soft mass of the tumor. The tumor projects into the cranial cavity for a distance of $2\frac{1}{2}$ ctm., in the form of an oval mass 5 ctm. long and $2\frac{1}{2}$ ctm. wide.

"The dural surface of the tumor is for the most part smooth and glistening. The dura can be traced over the surface of the tumor. It is evident that the tumor did not originate in the dura mater. There are places where the dural covering of the tumor is destroyed, and where the surface is rough and irregular.

"The part of the tumor corresponding to the external and the inferior surfaces of the petrous portion of the temporal bone is rough, and presents many bony spicules. It appears that the tumor is not complete upon this surface.

"A smooth, fibrous capsule, formed mostly by the dura mater, covers the intracranial part of the tumor, while no such capsule is present upon the basal and external surfaces.

"Upon section, the tumor presents a spongy texture. Interlacing trabeculae and membranous septa inclose little spaces, mostly minute, some as much as 2 to 3 mm. in diameter. Many of these spaces contain coagulated blood. To the naked eye the appearance is very much that of an angioma.

"Even after hardening in alcohol, the texture remains soft and spongy as that of the lung.

"Upon *microscopical* examination, it is found that the tumor is composed of a stroma inclosing myriads of spaces of all sizes, from microscopical dimensions to three millimetres. These spaces are lined with distinct cylindrical epithelial cells. Polypoid and dendritic processes, covered with cylindrical epithelium, project from the walls of many of these spaces into their interior, which they in part, or wholly, fill. This arrangement of cystic space, lined with epithelium and containing polypoid excrescences, resembles that in the so-called proliferous cystic sarcoma of the breast. As was evident to the naked eye, many of these spaces contained red blood corpuscles.

"The stroma of the tumor is composed of fibrillated connective tissue, tolerably rich both in fusiform and in round cells. In some places the stroma resembles mucoid tissue. This stroma is very rich in large and small blood-vessels. The walls of these blood-vessels contain little or no smooth muscular tissue. Particularly do many of the polypoid growths from the cyst-walls contain large blood-spaces, which sometimes occupy nearly the whole of the polypoid excrescences. It is evident that the blood in the interior of the cysts lined by cylindrical epithelium has come there in consequence of rupture of the blood-vessels and spaces in the cyst-walls. So rich are parts of the tumor in blood-vessels and irregular blood-spaces, that the structure may be described as angiomatous, although the greater proportion

of the spaces, which to the naked eye appear as blood-spaces, are glandular cysts filled with extravasated blood.

FIG. 3.

"In many places the stroma of the tumor contains a large quantity of yellowish-brown, granular hæmatoidin pigment.

"*Diagnosis.*—The tumor is a destructive cylindrical-celled adenoma. Parts of the tumor are also angiomatous. Such tumors are also described by some writers as cylindrical-celled epitheliomata (Cornil and Ranvier).

"Neither the gross nor the microscopical examination of the tumor affords any certain evidence as to the origin of the tumor. There would seem to be three possible sources of origin, namely: the dura mater, the bone, and the middle or internal ear. The relations of the tumor to the dura as above described are opposed to the idea of its origin in this structure, nor are similar tumors known to spring from the dura mater.

"The idea that a cylindrical-celled adenoma can spring from bone is so wholly opposed to the recognized views as to the origin of tumors that this source of origin may be rejected; the more so as there is nothing in the present specimen which speaks for this origin.

"There remains the origin from the middle or the internal ear, and this hypothesis may be accepted as the most probable, as in these parts are to be found cylindrical epithelial cells. In the tumor, however, none of the epithelium is ciliated.

"One may also think of Cohnheim's hypothesis as to the origin of tumors from misplaced or superabundant embryonic cells."

REMARKS.—The exceptional interest attaching to this case—no similar tumor, to my knowledge, having been described as occurring in just this situation—and the requests of some of my friends who have seen the specimen, have induced me to offer it for publication. Owing to the long continuance of the tumor, the facts bearing on its development and progress are somewhat meager, and gaps in the history of the case are numerous. On the other hand, many details, not without interest in the history, are omitted, not being essential to an understanding of the case.

In reviewing its history, it would seem probable that the tumor may have been in existence many years before finally proving fatal; thus, it will be noted that the patient had St. Vitus's dance in childhood, and was also subject to convulsions on ship-board while yet a youth. Nor must the causative influence of a purulent process in the middle ear be

overlooked in seeking for its origin, since its frequency in childhood is well known; such troubles, moreover, are frequently unrecognized or neglected.

So large a tumor connected with the skull is seldom seen, and, although intracranial growths are found, on making post-mortem inspections, which during life have given rise to scarcely any or no appreciable symptoms whatever, yet in this instance it is not so incredible that such an interesting train of phenomena occurred as that they should have existed for so long a time without a fatal result. This may have been in part due, however, to the slow growth of the tumor, which, indeed, at no time seemed to develop rapidly. After the tumor's appearance externally, it was at no time tender.

The patient always retained his appetite, notwithstanding the frequent attacks of neural nausea to which he was subject.

The tumor sought an outlet through the posterior wall of the external auditory canal as well as through the parietes of the skull, and, in fact, emptied itself through the cana after the operation at St. Luke's Hospital.

The acute aural catarrh which occurred now and then was an interesting feature, and early in the case masked the symptoms. This trouble manifested itself by the usual course of acute inflammation of the middle ear. The first attack noted in the history occurred in 1859, and gave rise to deafness and tinnitus aurium in the right ear. Of another attack, occurring in 1866, a more complete account is given; there were earache, loss of sleep, and a purulent discharge from the ear. In 1870 there was an attack of ten days' duration, and in 1875 a severe cold in the head was attended likewise with earache and discharge. The swelling said to have occurred on the "back of the neck" in 1871 was probably a mastoid abscess consequent on middle-ear trouble. These inflammations of the middle ear probably affected the progress of the tumor but little.

It is a remarkable fact that neither the invasion of the middle ear by the growth, nor the frequent attacks of acute middle-ear catarrh, should have destroyed the membrana tympani. The latter would doubtless have caused its perforation for the escape of pent-up secretions had not an outlet been afforded into the broken-down structures of the mastoid, and thence into the external auditory canal.

Vision.—The defect in sight first noted as beginning in 1872, and afterward as increasing in 1873, may have been due to the common changes of age, but the total blindness which took place a few months before death was owing to the presence of the growth.

The *psychical condition* of the patient was characteristic of brain tumors; he was depressed, secluded in manner, and wanting in energy. That he was scarcely ever free of headache or of some mental distress can well be imagined.

There was no aphasia.

Nervous Phenomena.—The presence of this tumor gave rise, naturally, to many neuropathic manifestations, to which it will only be necessary to allude: The first symptom of nervous disturbance occurred at the age of ten years, when the patient is believed to have had St. Vitus's dance. Soon afterward he was subject to convulsions. At the age of

twenty-five years the facial nerve was affected in its course through the petrous bone, causing Bell's palsy and difficulty in speech and deglutition. The right side was spoken of as "weakened" in 1875, and subsequently the right leg lost its power, and then the right arm.

The patient seems to have been treated for a long time for many symptoms without the presence of the tumor having been suspected.

The treatment adopted from the beginning after he came under observation at the Ear Dispensary was expectant chiefly; whenever the pressure of retained fluids gave rise to discomfort they were liberated, and drainage from the tumor was made as complete as possible. Nutrition was maintained and anodynes were administered when required. The utility of an operation was considered at the start, but, when the situation and nature of the growth were ascertained, it was deemed inadvisable to attempt its removal, although such a procedure has since been reported by Dr. Genzmer, of Halle ("Medical Examiner," May 3, 1877), in a fungus of the dura mater, which was unsuccessful.

TWO CASES OF MALIGNANT LYMPHOMA, WITH REMARKS.*

By LEWIS S. PILCHER, M. D.,

BROOKLYN.

CASE I.—Peter H., aged thirty-seven years, a native of Sweden, cabinet-maker by occupation, of robust physique, first consulted me in the early part of November, 1880, in consequence of a large tumor occupying the right side of the neck. It had first been noticed by him less than a year previous to this date. It had developed rapidly, and now extended from the margin of the inferior jaw downward two thirds of the way to the clavicle, and from the mastoid process forward to the median line of the neck, being bound down by the sterno-cleido-mastoid muscle, pushing the larynx over to the left of the median line, at times producing embarrassment of respiration and difficulty in deglutition. I removed the tumor, which was composed of a series of enlarged glands, on the 13th of November. Microscopic examination, as made by Dr. N. B. Sizer, revealed simply hyperplasia of pre-existing glandular tissue. The recovery from the operation was rapid and complete, and the man returned to his vocation as before.

At the end of two years, in the autumn of 1882, he again consulted me on account of an enlargement of the inferior inguinal glands of the left side, which he believed to have been excited by the frequent pressure against the corner of his work-bench to which they were constantly subjected while he was at work. This enlargement of these glands rapidly increased, so that by the first of the year 1883 the tumor seriously interfered with his locomotion. A marked impairment of his general health had also now become evident.

On the 27th of January, 1883, I removed this inguinal tumor, including also in the enucleation one of the external iliac glands; this was easily accomplished by prolonging the incision upward and outward in a curved direction upon the abdominal wall, and incising the deeper parts as for ligation of the external iliac artery. Union by first intention was secured throughout the operative wound, but the convalescence was made more protracted by attacks of severe pain in the abdomen; these were most severe at night; were not caused by, nor accompanied

with, tympanites; nevertheless, during the third week after the operation he was able to walk without fatigue or discomfort from his residence to my office, a distance of one mile. During the next three months the pain in the abdomen became more marked and continuous, requiring the daily use of morphine to render existence tolerable. A tumor could now be detected within the abdomen, situated over and to the left of the lumbar vertebrae, and evidently formed by enlarged retro-peritoneal lumbar glands.

Three months later the right inguinal glands had become so enlarged that they formed a tumor of some size. In the neck, likewise, on the side originally affected, below the mastoid process, at the angle of the jaw, and along the anterior border of the trapezius muscle, enlarged glands were visible. The patient was very desirous that these should be removed, and, at his earnest solicitation, both groups of enlarged glands were extirpated. This was done August 3, 1883. Union by first intention was secured in both localities, notwithstanding the cachectic condition of the patient.

Six weeks later a line of enlarged glands could be detected along the margin of the true pelvis on both sides. Ten days later, September 27, 1883, my last examination of him was made. His anæmia, as evidenced by pallor and increasing weakness, had become great. There was some oedema of the face, most noticeable mornings, with marked oedema of the outer side of the left thigh and of the scrotum. Examination of the urine gave negative results. There was no great appreciable enlargement of the spleen. He suffered much from abdominal pain, requiring increased amounts of morphine for its control. He walked about with difficulty. A few days later he sailed for Sweden, his native country, where, after a few weeks' longer suffering, he died from exhaustion, December 6, 1883.

From the first appreciation of any glandular enlargement to the time of death about four years elapsed. This time is divisible into three periods.

1. A period of primary localized glandular disturbance, extending over one year, and brought to an end by the first operation.

2. A period of quiescence of about two years. During this period the general health remained fair. He worked regularly at his trade and supported his family, but yet it was with more effort, and with less ability to endure than had been his former wont. There had taken place a very appreciable permanent impairment of his general strength.

3. A period of progressive anæmia, with diffuse glandular disturbance, extending through one year, and ending in death.

The chief medicinal agents that were used in the course of this case, in addition to the morphine, already mentioned, were preparations of iron and of arsenic, but no advantage could be discovered to be derived from them at any time.

CASE II.—Jas. R. T., aged twelve years and a half, a bright, studious, but somewhat delicate lad, whose father had died of laryngeal and pulmonary tuberculosis, and whose maternal grandmother had died of cancer of the breast. For a number of weeks the boy had been noticed to be somewhat languid, and in his general bearing to otherwise evince depression. One of the most noticeable signs of this consisted in a stiffness of the neck with which he frequently found himself affected on rising in the morning. Following upon this history he developed a croupy cough, which was most noticeable at night. This, being considered the result merely of a passing cold, was, for a week or more, treated by confinement to the house, and by simple domestic remedies. Nevertheless, the cough became more continuous, and paroxysms of severe dyspnoea had begun to occur at intervals when I was first called to see him, on the 30th of January, 1882. His condition was then similar, in general, to

* Read before the New York Surgical Society, November 25, 1884.

that manifested in the earlier period of a severe attack of catarrhal laryngitis, presenting fever, loss of voice, painful, dry, frequent, smothered cough, differing in this one respect of its muffled character from the harsher and more resonant cough of laryngitis. The breathing was somewhat labored and accelerated, with occasional exaggeration of the dyspnea. But, in addition, the gums were swollen and spongy, and the tonsils and the submaxillary glands were enlarged. The remedies usually efficient for the relief of catarrhal laryngitis were used during the first week of my attendance without benefit, beyond the alleviation caused by opiates. Meanwhile the swelling of the gums continued to become more marked until they were above the level of the teeth, and began to break down into spots of ulceration at many points. The same ulcerative process began to manifest itself in the tonsils likewise, and the pain on swallowing and on coughing was such as to indicate that the larynx was also the subject of ulceration. The condition of the mouth and fauces was such as to make a laryngoscopic examination out of the question. Now for the first time a general enlargement of all the lymphatic glands of the neck was noticed. These enlarged glands were not tender, nor was any one gland or set of glands greatly enlarged, the size of a hazel-nut, perhaps, being about that apparently presented by these glands. The general involvement of all these glands on both sides of the neck was such as to preclude the theory that these enlargements were due to the propagation of infection from the mouth or fauces, and to awaken in my mind the conviction that they were the expression of some general blood infection. While, therefore, the local troubles of the mouth and larynx were treated by stimulating and detergent gargles, and by insufflations of iodoform, special attention was directed toward antagonizing the evident general blood dyscrasia. For this purpose iodide of iron, cod-liver oil, and alcoholic stimulants were used. No effect upon the progressive march of the disease resulted from the remedies used. The ulcers in the mouth and fauces extended; the difficulty of swallowing increased; the croupy cough persisted, and was most harassing, while the labor of respiration was always marked. The condition of the glands remained unchanged, while pallor of skin and progressive debility marked the increasing impoverishment of the blood. No examination was made as to the condition of the spleen.

By the middle of the third week of my attendance the growing failure of the child's strength had reached such a degree that the greatest apprehensions as to a speedy fatal result were unavoidable. To what extent the undermining of the general powers might be due to the prolonged, laborious respiration, and to the sufferings caused by the functional activity of the swollen and ulcerated larynx, could not be positively estimated, but, inasmuch as there was a possibility that the chief cause of the dyspnea might be laryngeal obstruction, and nothing but good could come from diverting the respiratory current for a time from the ulcerated larynx, this was done on the seventeenth day after the lad came under my observation. The operation was attended by persistent capillary oozing from the surfaces exposed by the incisions. This was finally controlled by uniting together the edges of the tracheal incision and the skin incision on either side by sutures, thus accomplishing continuous pressure upon the raw surfaces. Only partial relief from the dyspnea was afforded by the operation. Though the child rallied fairly after the operation, the breathing became rapid and shallow after a few hours, and he died quietly, by asthensia, fourteen hours after the operation. No post mortem.

It is greatly to be regretted that the light which a post-mortem examination might have shed upon this obscure case was not obtained. I have but little hesitation, however, in classing it as a case of malignant lymphoma. The effect of the trache-

otomy was to demonstrate the intrathoracic location of the respiratory obstruction. The frequency with which dyspnea and cough are produced by the pressure of enlarged thoracic glands has long been recognized. Pressure on the recurrent laryngeal nerve may also have contributed to the spasmodic croupy attacks. The date at which the bronchial and other thoracic glands may have first begun to enlarge must remain uncertain, as a variable period may have been required to enable them to reach that stage at which obstructive and irritative symptoms, alternately produced by them, declared themselves. In the history of the case it was noted that a sudden and general enlargement of the glands of the neck took place. That some enlargement of these glands had not existed prior to the date of this discovery I would not assert. The peculiarity and interest attaching to them lie in the fact that so many of them, and these so widely diffused, were all at once noticed to have become enlarged, without being either painful or tender.

The early prominence of the stomatitis in this case is of interest in connection with the statistics of Gowers, in Reynolds's "System of Medicine" (1879, vol. v, p. 329, art. "Hodgkin's Disease"), where, in analyzing a group of cases in which the first symptoms depended, not on the glandular enlargement, but on the accompanying blood state, the statement is made that in two of these stomatitis was the earliest symptom. The appearance of the swollen gums in this case was unlike anything else I have ever witnessed. They formed a dull, livid, spongy ruffle, in which the teeth were set, giving the impression to the eye of tissue having a low grade of vitality, so that the melting down at points into complete necrosis was quite in keeping.

The two cases which have been detailed present the two extremes of chronicity on the one hand, and of acuteness on the other, that may be manifested by malignant lymphoma. A period of four years is far beyond the average time which intervenes between the first glandular enlargements and the final fatal termination, while a period of but little more than four weeks is quite unparalleled by any recorded cases of which I have been able to find mention. They both, however, presented, clearly marked, these essential features: A progressive blood deterioration, advancing steadily to a fatal termination, unaffected by remedies; and diffused, non-inflammatory glandular enlargements.

The differences of the accidents of the disease in these two cases were not greater than are often seen in other diseases which are recognized as being essentially of identical nature, as, for instance, tubercular disease of bones and of the meninges of the brain.

As to the etiology of malignant lymphoma, reflection upon the phenomena which attend its course leads one to put forth the hypothesis that the essential cause of the disease is a specific infecting micro-organism, upon the growth and activity of which the blood changes and the lymphatic glandular enlargements depend. The intensity and rapidity of development of the primary symptoms must depend on many things, and especially upon the original resisting power of the individual. Upon the special group of glands that may be first, or most largely, implicated in the localized gland-infection, will depend also many of the peculiar accidents of each case.

If, as is not impossible, each affected gland is, in turn, a new focus of active germ proliferation from which an increased dissemination of the special poisonous elements takes place, the early and repeated extirpation of the affected

glands would be a rational procedure, but this only as an accessory measure to those more general germicidal or antiseptic measures that might help to purify the blood stream itself, if any such can be found.

THE SIGNIFICANCE AND RADICAL CURE OF URETHRAL STRICTURE.*

By H. W. STREETER, M. D.,
ROCHESTER, N. Y.

I would call your attention especially to the following points: "The normal caliber of the urethra; the importance of stricture of large caliber; the common dependence of gleet, vesical irritation, and of various reflex symptoms upon such strictures; the frequency of stricture in the anterior part of the canal, and its infrequency in the deep urethra; the possibility of a radical cure by dilating urethrotomy, and its great advantages over dilatation in regard to safety, comfort, time, and permanency of results" (Otis). Stricture is a contraction or want of distensibility of the urethra. It is the product of inflammation in and just beneath the mucous membrane. It may be the slightest encroachment upon or a complete coarctation of the canal. Every hose-pipe is constructed smallest at the nozzle, to facilitate both retention and expulsion of its contents. The meatus is the narrowest part of the urethra. The normal caliber of the urethra is the caliber of the uncontracted meatus. Any instrument which will enter should pass the whole length freely. The term stricture is purely relative, and there is no fixed standard any more than there is for the mouth or vagina, for the hand or foot. The size of the penis and of the meatus should approximately correspond. It is maintained, as the result of many examinations, that there is a fixed relation of one to three and a half. I can see no reason why the bulbo-membranous junction should be taken as the gauge. It should be borne in mind that the meatus is more or less contracted in a great majority of cases. Stricture may be thread-like, or tape-like, or irregular, and there may be any number, from one to as many as the length of the canal affords space for. It may be located in any part except the prostatic. From the pathology of the disease, it should be found in greatest frequency where the preceding inflammation begins the earliest, rages the hottest, and lasts the longest—that is, in the anterior urethra—and such has been found to be the case. Deep spasmodic stricture can not be distinguished from organic, and yet will disappear upon cutting the anterior contractions. Otis places less than $11\frac{1}{2}$ per cent. of 258 strictures deeper than $4\frac{1}{4}$ inches, less than $5\frac{1}{2}$ per cent. deeper than $5\frac{1}{4}$ inches. The meatus is the point most frequently strictured. An ordinary-sized penis, which will only take an 8 or 9 English or 14 or 15 French sound, has stricture (Keyes).

One patient suffers and another does not, in accordance with the existence of gonorrhœa, balanitis, masturbation, excessive venery, or other excitants of inflammatory action and plastic exudation. While no advocate of indiscriminate incisions of the meatus urinarius, I believe that we

can not too carefully scrutinize every case, and that we should not neglect this condition as too trifling to be worthy of our notice, or omit to cut any meatus when contracted and accompanied by symptoms justly attributable thereto or for which there can be discovered no other cause. A very large proportion of all strictures are universally admitted to be located in the spongy, straight, or pendent urethra—i. e., within the first five or six inches. Most cases treated as deep organic stricture have no actual existence. The study of this point is worthy of our most serious consideration, and the establishment of the proposition does away, to a great extent, with one of the most serious of surgical operations—external urethrotomy behind the pubic curve—and also places among readily curable diseases a large class of cases otherwise incurable or little amenable to treatment. Gonorrhœa is the usual cause of stricture, although I think masturbation is much more frequently productive thereof than has been generally recognized. If the preceding inflammation persists for any length of time, the inevitable pathological process, "plastic effusion," commences, and, unless arrested, is certain to result in permanent narrowing of the canal, although the symptoms may or may not appear for a long time. Acute gonorrhœa, like other acute inflammations, is self-limited, and, if it persists or recurs without fresh exposure, there is a complication present which is inevitable, and must be appreciated and removed before the gleet can be pronounced permanently cured. That complication is stricture of the pendulous urethra, and the continuance of the discharge is due to arrest of the stream of urine and retention of a residual drop. It is especially important to recognize stricture in its earliest stages, while it is slight and soft and easily curable, and before it has become large and hard and productive of serious complications. The urethral walls must be kept supple and elastic, and the balance between the natural expulsive force and the friction along the urethra preserved, in order for the functions and secretions of the part to be normal. *As a rule*, gleet depends upon stricture, although the latter may exist without gleet. Henry Dick, of London, recognized this years ago. Sir Henry Thompson calls attention to its importance, and says it is often overlooked. Keyes and Bumstead indorse this opinion, and Otis says gleet *always* depends on stricture of greater or less degree. Frequent micturition is the next most common symptom; how common, is signified by its prevalence without any known cause, and resisting all treatment until the cause is removed. Its disappearance is one of the most remarkable and satisfactory results of internal urethrotomy. Other symptoms are nervous debility and irritability, chilly sensations, neuralgic pains of the testicles, cord, penis, bladder, perinæum, lumbar region, through the hips and thighs and down the legs, and in the soles of the feet, and may be as protean as the symptoms of uterine disease. As long ago as 1850 Civiale called attention to these reflex phenomena, dependent upon the slightest as well as upon marked strictures, and said their complete disappearance was so prompt after division of a slight stricture as to be almost incredible but for the frequent repetition of the instances. The slightest obstruction is liable to produce the gravest local

* A synopsis of a paper read before the Rochester Pathological Society, September 24, 1884.

and general symptoms. When we consider the anatomy of the genital organs and their intimate relation with and wonderful influence over all other parts of the body, as exemplified in our own daily personal and professional experience, we are *amazed*, not that so much is attributed to stricture, but that this relation was not recognized universally years ago, and that it is not more generally acknowledged even to-day.

The diagnosis is simple, yet in few conditions have more errors been made. In many cases of so-called kidney complaints, chronic inflammation of the neck of the bladder, enlarged prostate, nervous and functional disturbance of various organs, the pathological condition upon which they depend is never suspected. Far be it from the writer to attribute all urinary and reflex trouble to this cause; but there is, it will not be denied, a great deal of very careless diagnosing and hap-hazard prescribing for these complaints. There is no danger of our being any *too* particular or scientific in diagnosis, and we shall not lay too much stress on this subject if its consideration leads us to an accurate diagnosis of *something*, instead of covering up our ignorance and calming the patient's mind by vague and equivocal phrases. The unfavorable prognosis should never be pronounced until all the methods of modern research have been exhausted. In every case of gleet or frequent micturition or functional troubles of which the cause is not clear, the caliber of the urethra should be tested. No attention should be paid to the positive assertions of the patient that "he has no trouble of that kind," or to our own prejudices *pro* or *con*. If there is a doubt, the *experimentum crucis* should be made, for it is a matter of too great importance, both as regards our professional honor and our patient's welfare, to allow even the shadow of uncertainty to hang over the diagnosis. The proportionate size of penis and meatus, and the presence of a cicatrix or contraction, should be noted. The urethra should be explored with the bulbous bougie (and never should any other be depended upon, for it is impossible to make an accurate diagnosis with the common catheter or sound), and the location, thickness, and breadth of each stricture, if any exist, accurately measured. This instrument at once removes all doubt, and gives a most satisfactory sense of certainty, both physician and patient distinctly *feeling* any obstruction. Decided contractions are not liable to escape notice. It is the slight ones, especially at and near the meatus, which are very common, which have been and are often overlooked.

The object of treatment *has been*—first, to relieve the symptoms; second, to remove the cause, if possible. It *should be*, first, to remove the cause, and the symptoms will take care of themselves. As well attempt to remove a ligature tied around the penis by internal medication as to expect to remove an internal cord thereby. How large a proportion of cases of gleet have been treated by injections, balsam copaiba, and sandal-oil, and how inefficacious is such treatment, is well attested by the immense number of these patients infesting the land, wandering around from one doctor to another. While internal remedies may temporarily check the discharge, nothing short of a complete restoration of the canal to its normal caliber will effect a permanent cure,

no matter what the circumference of the urethra. Erosions are seated upon strictures, and are caused by friction and retained secretions, and applications thereto can only produce temporary, if any, benefit. The use of caustics with the idea of burning out a gleet or stricture has been very appropriately stigmatized by Liston as "most atrocious," and can only be harmful. Rapid dilatation by tying in a catheter is painful, barbarous, and unscientific. Little has ever been claimed for it.

Electrolysis, though extravagantly heralded as a cure-all in the journals, is not indorsed by Thompson, Otis, Bumstead, Van Buren and Keyes, Gross, Holmes, Althaus, or Beard and Rockwell, the leading English and American authorities upon stricture, venereal surgery, or electricity, or any other standard authorities with which I am acquainted, and by most of them is entirely ignored. My own experience with electrolysis, strictly in accordance with directions and after many years' practice, was devoid of any appreciable benefit. Professor Gross, in his recent elaborate article in the "American Journal of the Medical Sciences" on the analogous condition of stricture of the œsophagus, does not mention it. Electricity, like any other medicine, has to be used in definite doses or strength to produce definite effects, and there is no reason why the urethra should form an exception to this rule. By their sweeping assertions, the exponents of this method totally ignore the opinions and the skill of the great mass of the profession, and of the learned and experienced surgeons of our hospitals and colleges. The consummate assurance displayed in some of these statements can only be explained by a mistaken diagnosis, a misinterpretation of the effects of the electricity for that of the dilatation or other means employed in conjunction therewith, or by the promptings of interested motives.

Gradual dilatation is and has been the standard treatment. While palliative, it can not be, nor has it ever been asserted to be, radical. Most patients persist with it until they get tired out, and then only resort to it as occasion may require, never cured or expecting to be cured. It is agreed that the passage of the sound must be regarded, like a glass eye or wooden leg, as a necessary evil, likely to be continued at indefinite intervals during the remainder of life. The great majority of strictures are of large caliber at or near the meatus and within the pendent urethra; they are resilient and obstinate, and only require time to become tight contractions in many cases. There is no reason why dilatation should produce more than temporary benefit any more than in a similar external condition; in the latter it certainly would not be expected to do more. Divulsion is useless unless the stricture is ruptured. The passage of a full-sized sound (and any other is useless) is painful, repulsive, and liable to excite inflammation and leave the patient worse off than before. The passage of any instrument into the bladder is liable to be followed by urethral chills and fever, often serious when least expected. While thousands have been relieved by dilatation during an existence prolonged thereby, common humanity and professional pride alike forbid us to accept as the acme of our ambition *any treatment which cures only upon condition of its being continued for ever*. An external contracted band of tissue or a

strictured meatus is severed by the knife, without a thought of stretching, caustics, electrolysis, or other treatment.

There has been no reason why the analogous internal cord should not be divided, except the want, till comparatively recently, of suitable instruments. As with the external cord, the stricture must be completely severed, and as little adjacent tissue as possible. To accomplish this, the part must be rendered tense, and the blade concealed except while passing through the abnormal tissue. Bumstead, Keyes, and Otis emphasize the importance of strictures of large caliber, and agree practically as to the frequency of anterior ones and the necessity of cutting them before they can be declared cured, on account of their peculiar proneness to recontract after dilatation. Incising the straight urethra is a simple and safe proceeding, as shown by over fifteen hundred cases reported up to 1880, without a serious accident, by surgeons of established reputation. It is not so painful or dangerous as dilatation (with the full-sized sound passed into the bladder, as usually done), nor as continuous dilatation, nor as division. Little or no pain is complained of (the stricture being tense), subsequent hæmorrhage or inflammation is trifling, and the patient is not interrupted in the performance of his daily duties. The reflex symptoms are usually at once relieved and do not return, and the gleet disappears in a few days. If a repetition of the operation is required, it is due to imperfect division of the contractile band or to complications. It *should be radical* in every case, unless there are serious complications, and that it has been in a very large percentage is shown by the large number of cases reported, and re-examined at intervals of several years, by Professors Otis, Brown, Pease, and others. By relaxing the contraction and spasm, and allowing the irritation and inflammation to subside, the elasticity of the muscular coat of the urethra is restored, the circulation of the mucous membrane and submucous tissues becomes healthy, and the absorption of the effused product is promoted. While naturally incredulous of innovations, of the importance of strictures of large caliber, and of internal dilating urethrotomy, I have been convinced, by long experience, that its results in the treatment of stricture are not approached by any other method, and that it is founded upon common sense, a correct appreciation of the anatomical relation of the parts, of the pathology of the disease, and of the principles of scientific surgery.

BOOKS AND PAMPHLETS RECEIVED.

A Hand-book of the Diseases of the Eye and their Treatment. By Henry R. Swanzy, A. M., M. B., F. R. C. S. I., Surgeon to the National Eye and Ear Infirmary, etc. With Illustrations. New York: D. Appleton & Co., 1884. Pp. xv+437.

Éléments de pathologie chirurgicale générale. Par F. Terrier, Professeur agrégé à la Faculté de Médecine de Paris, etc. Premier fascicule. Lésions traumatiques et leurs complications. Paris: Félix Alcan, 1885. Pp. 419.

The Story of My Life. By J. Marion Sims, M. D., LL. D. Edited by his Son, H. Marion-Sims, M. D. New York: D. Appleton & Co., 1884. Pp. 471. [Price, \$1.50.]

Contributions to Surgery and Medicine. Part I. Intestinal Disease and Obstruction. London: H. K. Lewis. Pp. 284-xvi.

A Pharmacopœia for the Treatment of Diseases of the Larynx, Pharynx, and Nasal Passages; with Remarks on the Selection of Remedies and Choice of Instruments, and on the Methods of Making Local Applications. By George Morewood Lefferts, A. M., M. D., Clinical Professor of Laryngoscopy and Diseases of the Throat, College of Physicians and Surgeons, New York. Second Edition, revised and enlarged. New York and London: G. P. Putnam's Sons, 1884. Pp. iv+101. [Price, \$1.]

Forty-first Annual Report of the New York Association for Improving the Condition of the Poor, for the Year 1884.

Correspondence.

LETTER FROM WASHINGTON.

The Rag Importation Order.—The Providence Hospital Board.

WASHINGTON, November 24, 1884.

SECRETARY McCULLOUGH has made another change in the rag-importation order, of a very satisfactory sort. He had received the following petition, signed by a number of well-known New York physicians:

"We, the undersigned, recognizing the fact that there is great danger of the introduction of Asiatic cholera into the United States through the medium of old rags imported into the country and coming from European ports, do hereby respectfully suggest and urge upon you the necessity for immediate and decisive action in reference thereto.

"We are prompted thus to appeal to you because of the recent removal of restrictions on the importation of old rags, and it is our firm belief that this threatened danger can only be averted by the most thorough and systematic disinfecting of all old rags coming from any and all European ports," etc.

The Health Officer of New York, writing to the Collector of Customs at that port on the subject of the importation of gunny bagging, under date of October 25, 1884, said: "I do not think 'old bagging' should be classed among such merchandise as 'old rags.' The former is scarcely more objectionable as a carrier of infection or contagion than the bags in which many articles of merchandise are imported. The latter (rags) are notoriously not only filth carriers, but liable to contain the germs of disease, from the fact that they are often gathered from the streets, into which they may be thrown after being used by those sick of contagious or infectious diseases, or their attendants. That 'old rags' are not often cleansed before importation is proved by the confession of large importers at this port that they [rags] are 15 per cent. less in gross weight when properly cleansed."

The Medical Society of the District of Columbia, at its last meeting, after some discussion, unanimously voted the passage of a resolution setting forth that, in the opinion of the society, the prohibition of the importation of old rags from infected districts was a wise measure in the interest of the public health.

At the last meeting of the Providence Hospital Board, Dr. S. A. H. McKim was elected president, *vice* Dr. Grafton Tyler, deceased, and Dr. J. W. Bulkley was elected vice-president. Dr. J. H. Roberts was re-elected a member of the active medical staff.

NEW YORK, SATURDAY, DECEMBER 13, 1884.

THE PROCEDURE IN INSANITY CASES.

THE sensible procedure recently adopted in this State, providing for the settlement of the question of insanity in criminal cases before the trial of the prisoner on the main charge, has its counterpart in some of the Western States, and seems likely to render criminal trials more satisfactory than they have been in the past. In a recent case, in Wisconsin, it was stated that the law required that an investigation should be had in cases where there was a probability that the prisoner was insane, and that this should be had before his trial. This question was submitted to the jury, in the case referred to, and the point was, whether a jury trial on such matters was a right. The court held that this was not essential, and that the question could come before a jury or a commission specially appointed. In the Rhinelander case, in this city, the most recent case of importance in this State, the matter was referred to a commission, but, by a strange anomaly, the report of such a commission has no binding effect upon the court, which can accept it or reject it, in its discretion. In fact, in the Rhinelander case Recorder Smyth did reject the majority report, which declared Rhinelander insane, and adopted that of a single commissioner, to the opposite effect. Such a result would certainly not have happened if the question had come before a jury, as in the Wisconsin suit. Whatever the decision of a jury might have been, it would surely have been accepted as final.

It is an interesting inquiry, whether, under the Wisconsin law, if the matter had been referred to a commission instead of a jury, its report would have been conclusive and binding. The results in a number of recent cases, in which insanity has been held to have been established by the testimony of skilled witnesses, have not been wholly to the taste of the community, for in some of them the persons have afterward been adjudged to be perfectly sane. There is a feeling that the question of insanity can be decided quite as fairly by a jury as by experts, especially when the latter are called to sustain one side of the question or the other, and are not absolutely impartial. The opinion of the court, in the Wisconsin case, will be of interest as giving an historical statement of the usual procedure. It says: "The statute certainly did not give a jury trial as a matter of right upon such collateral issue. It says 'the court shall' make inquiry thereof in a summary manner, by jury or otherwise, 'as it deems most proper.' Undoubtedly it may, in a proper case, make such inquiry by a medical commissioner or otherwise. The method of making inquiry is left to the discretion of the court. So it appears that a trial by jury of such preliminary and collateral issue was not a matter

of strict right prior to the Constitution. 'There are,' said Sir Matthew Hale, 'two sorts of trials of idiocy, madness, or lunacy; the first in order to the commitment or custody of the person and his estate, which belongs to the King, either to his own use and benefit, as in the case of idiocy, or to the use of the party in case of accidental madness or lunacy; and in order hereunto there issues a writ or commission to the sheriff or escheator or particular commissioners, both by their own inspection and by inquisition, to inquire and return their inquisition into chancery; and thereupon a grant or commitment of the party and his estate ensues; and, in case the party or his friends find themselves injured by the finding him a lunatic or idiot, a special writ may issue to bring the party before the Chancellor or before the King to be inspected.' . . . Hence, where the return of the commission was unsatisfactory to the Chancellor, he would quash the same and issue a new commission. . . . 'It is a practice by no means uncommon in cases of lunacy,' said Lord Eldon, 'that, when the lunatic can not be removed to the jury, and it is inconvenient for the jury to go to the lunatic, one or two of the jury examine the lunatic and report their observations to the rest.'"

ALEXANDER'S OPERATION OF SHORTENING THE ROUND LIGAMENTS.

IN this ingenious age one must have rare originality to devise anything really new. Dr. Alexander, of Liverpool, must certainly be credited with this quality, for he has devised an operation for the permanent correction of inveterate and otherwise intractable retroversions of the uterus, which operation, simple as it seems in theory, appears to be quite original. As our readers are aware, the operation consists in shortening the round ligaments, which is readily done by cutting down upon them as they pass through the external inguinal ring, drawing them out to the desired extent, and then securing the "slack" in the wound.

The operation has now been performed about thirty times, and, so far as our information goes, without any bad results. As regards the correction of retroversion, it seems to be satisfactory, but it should not be forgotten that the cause of the condition is not done away with by it. On looking over the notes of several of the cases, we have been struck with the fact that, although the uterus was retained in its normal posture, it did not return to its natural size. This is an important matter, since it points to some other abnormal state (perhaps a laceration of the cervix) which ought to have been remedied before an attempt was made to cure the inclination.

It should be noted that the purpose of the operation is different in cases of retroversion from what it is in cases of prolapse. The idea is to exercise just enough traction upon a retroverted uterus to keep it in a position of slight anteversion, the weight of the overlying organs being the chief agent in preventing a return of the backward displacement. In prolapse, on the contrary, there is really a mechanical lifting of the organ by means of the round ligaments, which sooner or later will tend to yield to the strain. It is true that pessaries may be used

to relieve this strain, or colporrhaphy may be resorted to, but the probability is that the tissues will yield in time, as Dr. Emmet has shown to be the case after most plastic operations about the female genitals.

But the fact remains that Alexander's operation is a clever one, and nothing could be more frank than the manner in which its originator acknowledges its limitations. For the class of cases in which he recommends it, it is undoubtedly a most ingenious method of overcoming a condition that often proves intractable.

MR. GAMGEE ON MEDICAL CHARITIES.

We have received a copy of an address on this subject, delivered by Mr. Sampson Gamgee, of Birmingham, England. Mr. Gamgee's extended experience with the practical workings of the dispensary system has caused him to be regarded in his own country as an authority in the matter. The address deals with affairs of more than local interest, and the deductions drawn may be applied to some extent to our own medical charities. The point most urged is that out-patient relief has to a great degree ceased to be a true "charity," and is now dispensed in an indiscriminate and irrational way, "with the net result of doing the minimum of physical good and too often the maximum of moral harm"—quoting from the "British Medical Journal." Mr. Gamgee also aptly calls attention to the fact that, with the crowds that, under the present system, throng his clinic, the physician is "practically paralyzed for his best work." No one who has been engaged extensively in dispensary practice will deny that it stands in the way of careful diagnosis and treatment, however conscientious the medical attendant may be. The writer suggests as a remedy for the present abuses that the working classes, who contribute so largely to the support of hospitals, should be allowed to have an actual share in their management. Under this system, he thinks, not only will worthy applicants be recommended for relief, but the idle and shiftless will be prevented from "reaping where they have not sown." The key-note of Mr. Gamgee's address is, let the working classes be taught to feel that they are not mere objects of charity, but that they have a right to the aid of institutions which they themselves sustain.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 9, 1884:

DISEASES.	Week ending Dec. 2.		Week ending Dec. 9.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	45	12	19	14
Scarlet Fever.....	50	12	60	13
Cerebro-spinal meningitis...	9	9	3	3
Measles.....	111	20	126	20
Diphtheria.....	59	33	73	40

Free Trade in Contagious Diseases.—The "Evening Post" quotes from the London "Graphic" the following remarks apropos of a person recently elected to Parliament: "Professor Stuart is opposed to compulsory vaccination, and was heartily supported by all the Hackney anti-vaccinators. By the time that democracy wins all along the line we shall probably have strict protection against food and manufactures, but unlimited free trade in contagious diseases."

An Emergency Hospital.—It is announced that the Board of Apportionment has set aside the old Gouverneur Market for the use of the Department of Charities and Correction as an emergency hospital, in case of an outbreak of cholera.

The Essex County, N. J., Asylum for the Insane.—We understand that Dr. Livingston S. Hinkley, of New York, has been appointed Medical Superintendent of the asylum, which is situated in Newark. Dr. Hinkley was formerly connected with the New York City Lunatic Asylum.

The National Conference of State Boards of Health met in Washington on Wednesday, and the president, the Hon. Erastus Brooks, of New York, read an address, in which he called for increased work by the general Government in sanitation.

The Death of Dr. A. B. Craig, of Montreal, professor of medicine in the Montreal School of Medicine and Surgery, is recorded by the "Union médicale du Canada."

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from November 30, 1884, to December 6, 1884:*

IRWIN, B. J. D., Major and Surgeon. Granted one month's leave of absence. S. O. 112, Department of Arizona, November 28, 1884.

O'REILLY, ROBERT M., Captain and Assistant Surgeon. Assigned to duty as Attending Surgeon, Washington City, D. C., to date from October 20, 1884. S. O. 284, A. G. O., December 4, 1884.

BARROWS, C. C., First Lieutenant and Assistant Surgeon. In addition to other duties, to take charge of Medical Division Office, Department of Arizona, during absence of Surgeon B. J. D. Irwin. S. O. 112, Department of Arizona, November 28, 1884.

KNEEDLER, WILLIAM L., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort A. Lincoln, Dakota Territory, and ordered to Camp Poplar River, Montana Territory. S. O. 140, Department of Dakota, November 25, 1884.

PILCHER, JAMES E., First Lieutenant and Assistant Surgeon. To be relieved from duty at Camp Poplar River, Montana Territory, and ordered to Fort A. Lincoln, Dakota Territory. S. O. 140, Department of Dakota, November 25, 1884.

McCAW, W. D., First Lieutenant and Assistant Surgeon. Relieved from duty at Fort Wingate, N. M., and ordered to Fort Lyon, Col. S. O. 228, Department of the Missouri, November 26, 1884.

GRAY, CHARLES C., Major and Surgeon (retired). Died at Geneva, N. Y., November 26, 1884.

Society Meetings for the Coming Week:

MONDAY, December 15th: New York County Medical Association; Medico-Chirurgical Society of German Physicians of New York; Hartford, Conn., City Medical Society.

TUESDAY, December 16th: New York Academy of Medicine (Section in Theory and Practice of Medicine); New York Obstetrical Society (private); Medical Society of the County of Kings, N. Y.; Ogdensburg, N. Y., Medical Association.

WEDNESDAY, December 17th: Northwestern Medical and Surgical Society of New York (private); Medical Societies of the Counties of Alleghany and Tompkins, N. Y.; New Jersey Academy of Medicine (Newark).

THURSDAY, December 18th: New York Academy of Medicine; New Bedford, Mass., Society for Medical Improvement.

FRIDAY, December 19th: Roman Medical Society of New York (private); Chicago Gynecological Society (private)—Discus-

sion on Extra-uterine Pregnancy, to be introduced by Dr. William H. Byford, with a paper on "A Case of Interstitial Pregnancy").

SATURDAY, December 20th: Clinical Society of the New York Post-Graduate Medical School and Hospital.

OBITUARY NOTES.

Dr. Henry Austin Martin, of Boston, died on Sunday, the 7th inst., at the age of sixty. Dr. Martin was born in England, but came to this country at an early age, took his medical degree at Harvard in 1845, and thereafter practiced his profession in Boston, with the exception of the period of his service in the army during the civil war. He was a member of the American Medical Association, of the Massachusetts Medical Society, and of the Gynecological Society of Boston.

Dr. Martin had a preference for surgical practice, and the later years of his life were largely given to that branch, in which he displayed considerable originality. He was the promoter of the use of the solid rubber bandage and of the omission of the tube in the operation of tracheotomy. He was best known, however, for his long and careful study of all that pertains to the theory and practice of vaccination, and as having been the first man in this country to practice animal vaccination by the method that has now come into general use.

He was a writer of rare power, especially in controversy, but his published productions were not numerous. He was also a ready and forcible speaker. Earnestness was the chief trait of his character, as it must have appeared to those who met him by chance; but close acquaintance revealed a fund of humor and kindly feeling that made him very strong with the few who knew him well.

Letters to the Editor.

THE EMBARGO ON RAGS.

Boston, November 24, 1884.

To the Editor of the *New York Medical Journal*:

SIR: My attention was to-day directed to a letter from your Washington correspondent, appearing in the last issue of the "*New York Medical Journal*," November 22d, in which I find the following paragraph:

"It is sincerely hoped that the authoritative statement of the tracing of the Parisian epidemic to imported rags will for ever put at rest such mischievous assertions as that iterated and reiterated by the ragmen, that 'no epidemic disease has ever been traced to rags.' Even so straightforward a journal as the '*Boston Medical and Surgical Journal*' has given currency to this assertion, and has been unable to see any wisdom in the governmental order. It is hoped that those eminent sanitarians, the publishers, have not furnished the editorial eye-glasses."

Permit me to say that the insinuation conveyed by the last sentence is, as a matter of taste, a mean one, unworthy alike of the correspondent, if a member of our profession, or of the journal which publishes it. As a matter of fact, which is sufficiently well known to have made it easily possible for your correspondent to inform himself had he cared to, the publishers of the "*Boston Medical and Surgical Journal*" have nothing whatever to do with its editorial management. That journal is, probably, the only weekly medical periodical in this country, except the "*Journal of the American Medical Association*," which is owned neither by its publishers nor by its editor. Its position, therefore, enables it pre-eminently to speak on such

questions of general public and professional interest as the embargo on rags without fear and without favor.

The attitude we assumed in regard to the arbitrary embargo on rags we believe to be the correct one; we gave our reasons for it, and are ready to support it until convinced by facts or courteous arguments that we were wrong. To such we shall be always glad to give our attention. Had your correspondent offered any proof that the outbreak of cholera in Paris was due to old rags in bale, or, in fact, to *old* rags at all, or had he shown that cholera had positively ever been conveyed by such merchandise across the Atlantic, he would have furnished your readers with intelligence of real value.

It would, on account of various items therein, be perfectly simple for me to insinuate that your correspondent was "furnished with the eye-glasses" of the Surgeon-General of the Marine-Hospital Service when he wrote his letter, but I prefer to suppose that, whether good or bad, the "glasses" are his own, and that he at least believes them to be respectable and honest ones.

I should not ordinarily notice a mere *personal* matter of this sort. But the insinuation I refer to touches a subject of such general public importance, is found in such good company, and is so directly aimed at the integrity of the publication I represent, that no choice is left me. Begging you to give this letter the same publicity which you gave that of your Washington correspondent, believe me,

Very respectfully yours,

GEORGE B. SHATTUCK, M.D.,

Editor of the "*Boston Medical and Surgical Journal*."

SILK vs. CATGUT LIGATURES.

68 WEST FORTIETH STREET, NEW YORK, December 6, 1884.

To the Editor of the *New York Medical Journal*:

SIR: In your issue of November 29th Dr. Waterman details his experience as to the absorption of silk threads in the tissues, and suggests their use for the purposes now served by the "animal ligatures" of catgut, etc.

He asks others to report their observation in the matter. Of course, the filament of silk drawn from the bowels of the silkworm is as truly an "animal ligature" as the twisted intestine of a sheep. That the waxed, hard-twisted, braided silken cord, which by capillary absorption carries the products of decomposition into the interior of a wound, should excite suppuration, like any other foreign body, is not to be wondered at. It does not prove that the pure silk thread, made aseptic and kept so, will not be absorbed.

It occurred to me to make a trial in October last, when I happened to have a suitable and willing subject. Having done the operation for lacerated cervix uteri, and the patient being still anesthetized, the outer surface of the thigh was well washed with a solution of mercuric bichloride, 1 to 2,000. A fold of skin was lifted, and three threads were drawn through its base and cut off close to the points of entry and exit. Needle and threads had been first washed in a strong solution of carbolic acid. These threads were two sizes of am Ende's surgical catgut ligature, and soft, white surgeons' silk, three strands loosely twisted together. When the fold of skin was released and had flattened down, about three quarters of an inch of each cord lay in the tissues, half an inch apart and completely covered in. The part was dusted with iodoform and covered with a carbolyzed India-rubber plaster. Four days after, the plaster was removed. Over each cord of catgut was a slightly elevated and slightly reddened ridge; over the silk a lesser ridge and no reddening. Four days later, the ridges were less marked over the catgut, and the color was yellowish; over the silk, no ridge

or discoloration. Ten days later, the parts had entirely regained their natural condition.

These experiments indicate that pure, aseptic, loose-twisted silk may replace catgut in interior sutures and ligatures. We have also learned that, for operations on the vagina and perineum, and, for the most part, the sutures in laparotomy, silk may to advantage replace silver or iron wire.

W. M. CHAMBERLAIN.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

Meeting of November 25, 1884.

The President, Dr. ROBERT F. WEIR, in the chair.

Leuchæmic Lymphomata.—Dr. C. K. BRIDGON presented a patient illustrating a disease which he thought it was impossible to distinguish from malignant lymphoma, the subject of the paper of the evening, except by examination of the blood. A married woman, twenty-three years of age, showed extensive enlargement of the cervical lymphatic glands on both sides, the disease having existed for nine months. The glands in the right axilla also were enlarged, but enlargement of the glands elsewhere had not been detected. There was some enlargement of the spleen. Examination of the blood revealed a large increase in the proportion of the white-blood corpuscles. The enlargement of the glands affected first one side of the neck and then the other. Dr. Bridgon thought that most of the German authorities recognized the fact that it was impossible to distinguish the soft variety of malignant lymphoma from leuchæmic lymphoma except by examination of the blood.

The treatment had consisted of the administration of Fowler's solution in gradually increasing doses, beginning with three drops. The patient had not been under observation long enough to secure the full influence of the remedy.

Excision of the Entire Tarsus for Tubercular Osteitis.—Dr. W. T. BULL presented a patient upon whom he had operated more than six months before for tubercular osteitis of the bones of the tarsus, and removed the entire tarsus, with the exception of the posterior rim of the os calcis, the compact tissue of the bone. The result had not been very satisfactory. The patient was an Italian, twenty-two years of age, without constitutional vice. He entered the hospital on the 17th of last March, when he gave a history of having suffered from stiffness, swelling, and pain in the ankle for fifteen months, which finally broke out into sinuses, and the disease completely disabled him. On examination, there was found carious bone; the general condition of the patient was very good, and there was no evidence of tubercular deposit in any other part of the body. He was anxious to have the foot amputated, but Dr. Bull thought he might be benefited by conservative surgery, and therefore operated in the manner indicated. The wound healed satisfactorily so far as general symptoms were concerned, under peat and iodoform dressings, and the application of plaster-of-Paris splints. At the end of four months, however, the discharge continuing, Dr. Bull scraped out the sinuses, and in about one month after this operation they were all healed. Since then they had broken out once or twice, but were now healed. He could bear weight on the foot at the end of three months, but with pain. At present the limb was one inch shorter than the other, the calf of the leg smaller by two inches, the circumference of the instep less by three fourths of an inch, and the heel broader by one inch than the opposite heel. The foot was in

good position, and there was considerable power of flexion and extension of the metatarsus. The patient walked, with a slight limp, upon a thick-soled shoe. He was working in a grocery store, but had pain enough at times to interfere with his work. It should be remembered that there was left behind a thin shell of the os calcis, through which one drainage-tube passed, and the continuance of pain might be explained by inflammation in this bone. It was possible that the functions of the foot might improve, as the man had had a proper shoe but a few days. Judging from the present condition, Dr. Bull was compelled to think that amputation at the ankle joint would have been a more rapid means of cure, since that would have given, with a good artificial foot, facility in walking. But the man was hardly in a position to provide himself with that luxury. Dr. Conner, of Cincinnati, had reported last year to the American Surgical Association two very favorable results after complete excision, and Dr. Bull had been stimulated, by a perusal of his very thorough paper on the subject, to try conservatism in preference to amputation.

Dr. Bull referred to another case, that of a married woman, twenty-five years of age, who had about the same condition of the tarsus, but there was, besides, evidence of disease of the tibia and fibula. He not only removed the bones of the tarsus, but sawed off the lower ends of the tibia and fibula, yet the patient was never able to walk at all except by the aid of artificial support, and the limb was finally amputated. He thought that the testimony afforded by these two cases was certainly not very satisfactory with regard to extensive resection of the bones of the tarsus.

Two Cases of False Joint (Esmarch's Operation) for Ankylosis of the Jaw.—The President presented two patients on whom Esmarch's operation had been performed for the establishment of a false joint in the lower jaw, on account of ankylosis. The first patient was a woman, thirty-three years of age, who, ten years ago, while cleaning windows, fell, striking her chin and the left side of the face on an iron bar. Much swelling followed, causing at first difficulty in closing the jaws, and subsequently inability to open them. At the end of a year she was compelled to subsist on fluid diet. In September, 1878, she entered St. Vincent's Hospital, where the cicatricial bands were divided and separated freely from the jaws, and the mouth was forcibly opened. In spite of wedges subsequently used, recontraction took place, as was commonly observed. In May, 1879, at Bellevue Hospital, the cheek was split open from the mouth, the bands were cut out, and mucous membrane was brought over the gaps. As a great deal of neuralgic pain was experienced after this, another section of the cheek was made, in March, 1880, without benefit. When she came under Dr. Weir's charge the separation of the jaws amounted to one quarter of an inch, and there were several strong internal bands stretching from one jaw to the other from the angle of the mouth outward. A slight motion was perceived. The cicatrix in the cheek was nearly at the posterior margin of the masseter, was, at its posterior part, exquisitely sensitive, and was the focus of severe and constant neuralgic pain. On January 29, 1883, by an incision over the lower edge of the bone, one inch and a quarter of the left side of the lower jaw was removed, starting from the second bicuspid tooth of that side, a slender cicatricial band being purposely left attached to the mental end of the maxilla, to act as a ligament for support. The painful cicatrix was at the same time dissected out. Complete relief followed the operation, and she was able to masticate readily within a week therefrom. Three months later a return of pain was felt in the mouth, supposed at first to be due to some carious teeth in the upper jaw, which were removed. It was, however, found to be due to the pressure of the distal end of the inferior maxilla, from the persistent

action of the pterygoid muscles. This portion of bone was eventually removed, and the patient had since been free from pain, and able to eat well. It was now more than three years since the final operation, the jaws opened to a normal width, and, thanks to the cicatricial band, which was preserved, the chin kept its median position.

Dr. Weir's second case was that of a boy of sixteen, who was admitted to the New York Hospital in October, 1882, having, nine years previously, received a lacerated wound over the left temporo-maxillary articulation, which resulted in obliteration of all motion in this joint. He had had his jaw opened two years previously, under an anæsthetic, by screws and presses, but the relapse was speedy. Dr. Weir removed a wedge-shaped piece of the lower jaw by an external incision extending from the second bicuspid tooth outward. The piece of bone removed measured half an inch along its upper and three quarters of an inch along its lower edge, and gave perfect freedom of motion. On the third day the boy was able to move the jaw freely. The opening of the mouth was now normal as to extent, though there was slight underlapping of the lower incisors. Lateral mastication was perfect.

Dr. L. S. PILCHER, in connection with the first patient presented by Dr. Weir, reported a method which he adopted in the case of a little child, four years of age, whose jaws were locked together firmly, as a result of cicatrices produced by extensive pytialism some years previously. There was a dense cicatricial mass which extended from opposite the canine teeth backward to beyond the molars, fastening the jaws together. Dr. Pilcher operated by making an incision from the angle of the mouth outward until he had divided the entire mass freely. He then dissected up the cicatricial tissue from the jaw, both above and below, and excised it. He then took a flap from the mucous surface of the upper lip, and, having turned it backward, planted it upon the surface exposed along the upper jaw, as the result of excising the cicatricial mass, and fastened it in position with sutures. He treated the lower lip in the same way, taking a flap from it, turning it back, and planting it upon the freshly exposed surface. He then brought the cheek together in such a manner that the edges of the mucous membrane of the flap above and below were nearly in apposition, and, as a result of it, there was a new mucous surface filling the space from which he had removed the cicatricial mass. There was promise of considerable relief from the original contraction. Most excellent union had taken place. It was perhaps a month since the operation was performed, and the child's condition was very satisfactory. The amount of recontraction which might take place was, of course, uncertain, but it had seemed to him that, with watchfulness and daily separation of the jaws, any slight tendency to recontraction, due to cicatricial tissue which might have been left in the excision, could be prevented. He mentioned it as possibly a method which might take the place of resection of the jaw.

Malignant Lymphoma.—Dr. PILCHER read a paper on this subject. [See page 663.]

Dr. H. B. SANDS thought that, in the absence of any histological information in one of Dr. Pilcher's cases concerning the nature of the morbid growth, and in view of the striking difference in the clinical histories of the two cases, there might be a reasonable doubt whether in both the character of the disease was identical. As he understood the term malignant lymphoma, it did not imply a peculiar abnormal structure, as was observed in carcinoma and sarcoma. The malignancy of the disease was characterized by its wide dissemination, and by the appearance of hyperplastic glandular tissue in some parts of the body where normally no lymphatic glands existed. He thought, therefore, it was fair to inquire whether the first of Dr. Pilcher's cases may

not have been one of multiple lymphoma, and the second one of lympho-sarcoma, which was a truly malignant affection, characterized by much more rapid progress than was usually observed in cases of multiple or malignant lymphoma.

Dr. PILCHER said that he had attached the word malignant to these cases rather with reference to the steady progress of the disease toward a fatal termination without being affected in its course by remedies. The peculiarity of the cases called malignant lymphoma consisted in these glandular enlargements in which nothing more was found than normal gland tissue, with fibrous and cellular elements—hyperplasia of the ordinary gland tissue. The second case he had reported with special hope that it might be criticised because of its obscurity, and it was only by association with the various symptoms and conditions present that he was able to reach any satisfactory conclusion concerning its exact nature.

Dr. BRIDGES thought the term malignant lymphoma had been attached to the disease not so much on account of the histological elements present as on account of the inveterate character of the affection clinically. He had never seen a case in which the disease ran its course in three or four weeks, and he should look upon the second case reported by Dr. Pilcher as one of glandular enlargement secondary to the ulcerative process going on in the buccal cavity.

NEW YORK ACADEMY OF MEDICINE.

(SECTION IN OBSTETRICS AND DISEASES OF WOMEN AND CHILDREN.)

Meeting of November 27, 1884.

Dr. ALEXANDER S. HUNTER, Chairman.

Anteflexion of the Uterus and its Associated Pathological Conditions; their Prevention and Treatment.—Dr. W. GILL WYLIE read a paper with this title, which was the continuation of a paper contributed by him to the "American Journal of Obstetrics" for September, 1883. After a brief summary of that paper, he proceeded to the consideration of the prevention of anteflexion. This depended upon its ætiology, chiefly reducible to defective general health during childhood, leading to insufficient and imperfect development of the genital organs. To counteract this tendency of puny children, they should have good food, fresh air, and opportunity for exercise, and their moral and mental surroundings should also be made wholesome. It was surprising how much could be done for delicate children by attention to hygienic details. Corsets, especially those which extended below the waist, certainly tended to displace the uterus, and might increase anteflexion. If it was begun at an early age, lacing was capable of doing great harm, of a character so insidious that it was not noticed at the time. Local treatment was hardly applicable as a preventive, for the condition was generally ascertained only when its effects began to show themselves.

It was usually on account of painful or irregular menstruation, or sterility, that curative treatment was sought for. If the menstrual derangement resisted general treatment, he usually began local treatment by inserting a small piece of borated cotton saturated with glycerin against the anterior lip of the cervix, crowding it backward somewhat in the vagina. This tended to form a ball which would press the cervix backward and lift the body of the uterus. The patient was to remove the cotton at the end of twenty-four hours, by means of a string attached to it. The glycerin softened the tissues, by reason of the profuse watery discharge it caused, thus improving the pelvic circulation, and it tended to relieve over-sensitiveness. The application was to be repeated two or three times a week, until a vaginal examination could be made without giving pain,

and the hot-water douche was to be used in the intervals. If there was any congestion or subacute inflammation in the tissues about the uterus, instead of using simple glycerin, the cotton was saturated with a mixture one part of alum, fifteen parts of glycerin, and enough carbolic acid to act as a disinfectant, generally about an ounce to the pint; and the wads were gradually increased in size. In two or three weeks it would be found that the vagina was larger and less sensitive; the cervix softer and less conical, and directed more backward; and the parametric tissues less sensitive and not so rigid as before. These results might require a longer time to bring about, especially where the disease had been of long duration. When they had been accomplished, the next step was to dilate the cervical canal with Sims's dilator, having previously sponged out the vagina with a 1-to-3,000 solution of bichloride of mercury. The instrument, if of the proper curve, could be introduced almost as easily as a sound. The blades should be spread to the width of about two lines. This sometimes would require considerable force in cases of long standing, and in some instances it caused intense pain, like that of menstruation. After withdrawing the dilator, the surgeon should pass a cervical protector up to the os internum, and through it pure carbolic acid should be thoroughly applied to the os internum by means of an applicator armed with cotton. As the speculum was removed, about twenty grains of powdered iodoform were to be blown against the cervix, and this would often relieve the pain at once. He had never seen this procedure do any harm after the proper preliminary treatment and the use of antiseptic precautions. It was generally best not to repeat the dilatation in less than a week, and two or three dilatations would usually be sufficient. It might be well to do the first one at the patient's home, so that she might rest in bed after it. The degree of dilatation should be increased each time, until the blades were separated to the extent of four lines. The dysmenorrhœa would then be found to be relieved, and in favorable cases the beginning of a permanent cure made. As to this, much would depend on the state of the general health.

Sometimes this treatment failed to cure sterility, although it might have put a stop to the dysmenorrhœa. It was then necessary to perform Sims's operation with his metrotome, which Dr. Wylie had made with blades so curved that they were easy of introduction. The blade was directed backward, and the posterior wall of the cervix was incised up to the os internum, and cut completely through for the lower half-inch or more, according to the amount of projection of the cervix into the vagina. He did not find it necessary to make an anterior incision, but trusted to dilatation to overcome all constriction at the os internum. For the plug, to be used afterward, he preferred one made of hard rubber. Even after making an anterior incision, according to his experience, the use of a dilator was necessary before a full-sized plug could be passed into the corporeal cavity, and unless it could be so passed, and unless it would stay there of itself when once inserted, the inference was that the end of the plug did not really extend beyond the os internum. To this failure no doubt many cases of want of success were to be attributed.

The author then described the details he employed, as to cleanliness, disinfection, etc., in the after-treatment, and added that the risk from this operation was very small, if due precaution was observed as to the proper preliminary treatment, and if care was taken not to divide the cervix too freely, and it was a very successful procedure. If the dilatation was only imperfectly done, of course the relief would be only temporary, but if it was done thoroughly, and repeated if necessary, a permanent cure would often result. Childbearing, however, was the best means of overcoming the deformity, and, that being the

case, early marriage was to be recommended for women so affected, as sterility was not so likely to be caused early as subsequently. Sponge-tents were more dangerous and less effective than mechanical dilatation, and graduated sounds, especially if they were nearly straight, were not to be recommended. The author was unable to see the advantage of bilateral division of the cervix. He was also, in general, averse to the use of pessaries for antelexion, especially stem-pessaries.

The paper closed with the following conclusions: 1. In a certain number of cases of marked anterior curvature no painful symptoms are produced. 2. Anterior displacements are the result rather than the cause of uterine disease, but they may intensify such disease. 3. The dysmenorrhœa is rarely due directly to the flexion, but the latter may aggravate the real causes. 4. Mechanical supports are only palliative, unless the cervix is dilated and complications are treated at the same time. 5. In most cases, imperfect development of the uterus is the fundamental lesion. 6. The general health, therefore, should be improved, and stenosis should be overcome.

NEW YORK CLINICAL SOCIETY.

Meeting of October 24, 1884.

Dr. J. WILLISTON WRIGHT in the chair;

Dr. W. DUNCAN McKIM, Secretary.

Empyema.—Dr. A. A. SMITH related the history of a case. The patient was a man, twenty-two years old, who, except for an attack of acute rheumatism at the age of six years, had always been well. December 18, 1883, after a supper of lobster salad, he went to bed feeling perfectly well. He awoke about 2 A. M. with a severe chill, accompanied with violent vomiting and purging, also pain in the left side. Dr. Smith saw him about three hours afterward. The chill had then passed off, his temperature was 103.5° F., the pain in his side was severe, and he was still vomiting and purging. There was also some delirium. It took nearly a grain of morphine, given hypodermically, to quiet the pain. In a few hours there were all the evidences of a pleuro-pneumonia, which ran the usual course, and in a week convalescence seemed to be fully established. On the eighth day he had a moderate chill, followed by fever and increased pain in the chest. The temperature now ran up to 105°. This was so unusual that Dr. Smith made frequent and careful examinations, and found within the next few days that the physical signs, which had been those of the third stage of pneumonia, were gradually giving place to those of pleural effusion. From the persistent and marked constitutional disturbance, it was suspected, also, either that some other organ was becoming diseased, or that the fluid in the pleura was not serum. The first week in January a hypodermic syringeful of pus was withdrawn. On the 15th, twenty ounces were removed with an aspirator, being as much as could be obtained. The patient then improved steadily; a year before, he had weighed 172 pounds, just before the attack 165, after the illness 125, and at the present time 164. The recovery after a single aspiration was of interest in view of the nature of the fluid. Probably the pus was sequestered.

Dr. E. G. JANEWAY mentioned a case of pleurisy with serous effusion on one side and purulent on the other, in which recovery had followed a single aspiration.

Dr. BEVERLEY ROBINSON thought it generally advisable to tap once or twice before resorting to incision.

Dr. L. EMMETT HOLT raised the question whether it was not better to make frequent aspirations than to remove the whole of the fluid at once. He had lately been experimenting in the matter, withdrawing about five or six ounces at short intervals.

He was careful to disinfect the needles thoroughly, and in no case had suppuration been caused by this frequent aspiration.

Dr. JANEWAY was accustomed to let the flow continue until the patient showed signs of distress.

The CHAIRMAN had seen several alarming cases of dyspnoea after withdrawing a large quantity of fluid, such as a pint.

Dr. SMITH thought that the mere withdrawal of a syringeful for diagnostic purposes, often seemed to hasten absorption when the fluid was serous.

Pleurisy with Effusion; Superficial Gangrene.—Dr. W. H. KATZENBACH read the notes of the case of a woman, sixty years old, subject to attacks of acute intercostal neuralgia, who was attacked on the 3d of October with severe pain in the left side. A hurried examination failed to reveal any intra-thoracic trouble. An opiate was ordered, and the patient was requested to summon him the next morning if relief was not obtained. He was not called until the 8th, and he then saw her at 4.45 P. M., when she was propped up in bed, groaning with pain, and presenting an extremely anxious expression. Her face was pale, the surface was bathed in perspiration, the finger-nails were blue, and the pulse was rapid and weak. Physical examination revealed flatness over the whole left chest, and displacement of the heart to the right of the median line. Two thirds of a grain of morphine, given hypodermically, relieved the pain. Through the night the pulse remained rapid and weak, but hypodermic injections of brandy and black coffee, and brandy by the mouth, increased its force. At 11.30 A. M. on the 9th the pulse was 140, the respiration 26, and the axillary temperature 100° F. At 4.45 P. M. the pulse was 138, the respiration 26, and the temperature 100.5°. On the 13th the chest was aspirated, and fourteen ounces of yellow serum were withdrawn. The operation was attended with no discomfort, and was followed by considerable relief.

About this time a gangrenous sore appeared over the coccyx, from which foul sloughs were separating at present. The pleurisy was clearing up, and to-day there was no evidence of fluid in the cavity. The patient had not been in good health through the summer, and to that fact, in addition to the attack of pleurisy, the sore was attributed. It was not due to pressure, for she had never been able to lie on her back.

The points of interest were, the occurrence of acute pain while the effusion was at its height, and the gangrenous sore in the locality mentioned.

Photographs of the Larynx.—Dr. D. BRYSON DELAVAN showed some photographs of the larynx, taken by Dr. Thomas R. French, of Brooklyn, and stated that attempts at laryngeal photography had been made by Czermak, twenty years ago, and by Lennox Browne, three years ago, but that Dr. French was the first to succeed in photographing the larynx without including the mouth or the fauces. This, Dr. Delavan thought, would constitute an era in the study of the physiology and pathology of the larynx.

Dr. ALLAN McLANE HAMILTON presented a photograph of a hand, that of a patient with progressive arthropathy.

Dr. DELAVAN then read an account of the Copenhagen meeting of the International Medical Congress.

NEW YORK ACADEMY OF MEDICINE.

Meeting of December 4, 1884.

The President, FORDYCE BARKER, M. D., I. L. D., in the chair.

A Donation to the Library.—Dr. HUDSON, of the Library Committee, presented over fifty volumes of medical works, given to the library by Dr. C. R. AGNEW.

Nominations for Office.—The PRESIDENT said that he wished

to preclude any possibility of his being renominated for the presidency by saying (however delicate it might be to make the statement) that he would have to absolutely decline to accept the nomination, as it would be impossible for him to discharge the duties of the office if he were elected. It was only under urgent circumstances that he had been persuaded to accept the office during the past term, and he must positively refuse to allow his name to come before the Academy again.

Dr. AGNEW briefly recounted the important services rendered the Academy by Dr. SAMUEL T. HUBBARD, and said that he knew of no one among the fellows who was more entitled to their suffrages to succeed the present honored President. He therefore nominated Dr. Hubbard for the office of President.

Dr. ABRAHAM JACOBI, Dr. W. T. Lusk, Dr. T. G. THOMAS, and Dr. AGNEW were also nominated for the office of President.

For the Vice-Presidency, Dr. C. C. LEE and Dr. T. A. EMMET were nominated.

Dr. II. T. HANKS declined a renomination. For the office of Corresponding Secretary, Dr. P. F. MUNDE, Dr. H. KNAPP, and Dr. L. ELSBERG were nominated. Dr. W. M. CARPENTER declined a nomination.

For the office of Trustee, Dr. A. L. LOOMIS, Dr. J. W. WRIGHT, Dr. E. ELIOT, and Dr. F. H. HAMILTON were nominated.

For members of the Committee on Admission, Dr. W. M. McLAURY, Dr. S. D. POWELL, Dr. A. S. HUNTER, Dr. C. A. LEALE, Dr. L. ELSBERG, and Dr. J. A. WYETH were nominated.

For members of the Committee on Education, Dr. J. D. BRYANT, Dr. F. R. STURGIS, and Dr. S. SMITH were nominated.

For members of the Committee on Medical Ethics, Dr. A. HADDEN, Dr. A. S. HUNTER, Dr. T. G. THOMAS, Dr. T. E. SATTERTHWAITE, and Dr. A. H. SMITH were nominated.

For members of the Committee on the Library, Dr. HUDSON and Dr. G. M. LEFFERTS were nominated.

Is the Operation of Tracheotomy in Diphtheritic Croup dangerous?—When should the Operation be performed?

—Dr. JOSEPH E. WINTERS read a paper with this title. The opinion that tracheotomy was a dangerous surgical operation he believed had no valid foundation, and should not be accepted with the confidence with which it seemed to have been received in this hall in March last. He quoted from Mr. Holmes, who represented the operation as a very dangerous one, but said that in one of Mr. Holmes's three fatal cases death was due to what would be called a too nimble tracheotomy, and in another complications arose from inserting the tube into the cellular tissue outside of the tracheal opening, and he regarded comment upon Mr. Holmes's tracheotomies as unnecessary. Professor Gross, in one part of his work on "Foreign Bodies in the Air-Passages," expressed his opinion of tracheotomy in the class of cases coming under the subject of the paper as very dangerous, and yet quotations elsewhere from the same volume showed that the author was contradictory in his own statements on this point, and it nowhere appeared in this work that he had ever performed tracheotomy for diphtheritic croup. Billroth, some years ago, at a time when there was no evidence that he had performed tracheotomy for diphtheritic croup more than a dozen times, had expressed an opinion that the operation in these cases was a dangerous one, but there was nothing in his more recent writings which would indicate that he any longer entertained this view.

The author quoted from numerous writers on the subject of tracheotomy, particularly for diphtheritic croup, some of whom had lived in ancient, some in modern, and some in quite recent times, and most of the quotations went to show that tracheotomy in diphtheritic croup was not a dangerous operation. Trousseau had performed the operation two hundred times without a single accident, except in one case in which the patient died as soon as an incision through the integument had been made.

Bretonneau did not speak of the operation as a dangerous one, nor of skill in its performance as necessary to success. Barthéz did not regard the operation as dangerous; and a quotation to the same effect was made from West, Meigs and Pepper, and others. Dr. Winters did not regard the entrance of a small quantity of blood into the trachea as dangerous; on the contrary, many operators recommended that a little blood be allowed to enter the trachea in order that violent cough might be induced, which would expel viscid mucus and fluids.

The operation of tracheotomy in itself not being dangerous, nothing connected with its mere performance should deter us from resorting to it when it was indicated. In a large proportion of cases of diphtheria which terminated fatally, death was due to obstruction of the passage of air into the lungs, and the object of tracheotomy was to overcome this difficulty. When the operation failed to save life, generally the reason would be found to lie in the fact that it had been postponed too long, in complications existing in the bronchi or lungs, in sudden collapse, in asthenia, or in want of careful after-management. Suppuration in the anterior mediastinum, erysipelas and gangrene around the wound, and slipping of the cannula into the tracheal opening, had very seldom occurred. Writers did not speak of diphtheria of the tracheal wound as taking place often. As to the influence of the operation on the cure of croup, the admission of air into the lungs through an artificial opening into the windpipe secured for the diseased larynx entire rest, and thus led to a suspension of the diseased action there. In cases in which the patients had died from other causes than asphyxia some time after the operation had been performed, the pseudo-membrane was found to have disappeared from the larynx; but, in cases in which death had taken place within a few hours after the operation, the membrane still existed. It therefore appeared that, in cases in which patients got well after tracheotomy, the restoration of the larynx to a healthy condition was rapid. The diphtheritic process stopped at the level of the vocal bands more commonly than was supposed, and, when it extended into the larynx, trachea, and bronchial tubes, it was by direct propagation from above downward, and not by simultaneous affection of the entire air-passages. If tracheotomy for diphtheritic croup was not dangerous; if it met the complication of obstruction to the entrance of air to the lungs, and was promotive of cure of the affection; if the specific disease was not aggravated by the operation, and the false membrane very rarely developed at the wound, the operation certainly brought with it no added element of danger, and the next subject which would come up for consideration was that of delay in its performance. The author then quoted from Trousseau and others, to show that a considerably larger proportion of patients upon whom the operation was performed recovered than of those who did not receive its benefits. He could not conceive of a case in which delay would not be dangerous. We could gain nothing by delay, while the success of the operation would be largely interfered with. When the rima glottidis was obstructed, less air entered the lungs, with every inspiration the lungs became less expanded, the circulation of the blood became embarrassed, imperfect oxidation produced violent constitutional disturbance, the entire body became cyanosed, passive congestion and oedema occurred in the respiratory organs, and yet it had been advised that these immediate precursors of death should be allowed to appear before resorting to tracheotomy! One might with equal propriety postpone the operation for strangulated hernia until after the development of gangrene. In the majority of cases of croup the patient died of want of oxygen; the object of tracheotomy was to render oxygen accessible to the lungs, and every breath of air which the child could take tended toward a cure; we should not, there-

fore, wait until the patient's strength had been exhausted in gasping and struggling for breath before resorting to tracheotomy. He would resort to the operation as soon as ipecac and other ordinary remedies had failed to produce relief. The tender age of the patient should not contra-indicate the operation, but rather—as in these cases the disease advanced with much greater rapidity, and as there was greater liability to bronchial and pneumonic complications—the operation should be resorted to earlier.

Early age, previous ill-health, especially chronic catarrh, and bronchial and pulmonary changes, made the prognosis more serious, as did also measles, scarlet fever, and nasal diphtheria. When croup came on very early in the disease, making its appearance suddenly and producing marked obstruction, the prognosis was more serious. When the glands of the neck were much enlarged, the operation proved less generally successful. It was an unfavorable sign if the breathing did not become perfectly free and regular after the operation, as it indicated some obstruction below the artificial opening.

The after-management was more important than the manner in which the operation was performed. Careful attention should be given to removing any obstruction to the cannula, the patient's powers should be sustained by proper food and stimulants, measures should be adopted for subduing local processes, and attention should be given to the temperature and moisture of the room.

The general practitioner should not, in a case of threatening strangulation from croup, search for a surgeon to open the trachea, but should proceed to perform tracheotomy himself without any delay.

The following were some of the conclusions which the author had reached: 1. Tracheotomy of itself, performed with care, involved little, if any, danger to life. 2. Accidents during the operation generally resulted from want of care. 3. It prevented asphyxia, and thus gave more time for the administration of remedies and to enable the system ultimately to throw off the disease. 4. It prevented laborious and rapid breathing, thus tending to prevent exhaustion. 5. It allowed of a free supply of air, and thus assisted in curing the original malady. 6. It was a simple resource by which the condition of the patient was not likely to be rendered worse. 7. Having made a diagnosis, we should not delay the operation, as this was the chief cause of failure in unsuccessful cases. 8. We should operate slowly, deliberately, and without hurry, and not lay open the windpipe at one sweep of the knife. 9. It was seldom that either the constitutional condition or special causes contra-indicated the operation. 10. It alleviated suffering. 11. It mitigated symptoms. 12. It prevented complications. 13. It never added dangers to the original disease. 14. Statistics showed that nine tenths of the patients requiring the operation were suffocated without it. 15. No patient who had lived without the operation would have died had it been performed. 16. The dictates of conscience, of facts, and of common humanity united in demanding the operation.

Dr. J. WILLISTON WRIGHT had never regarded tracheotomy as specially difficult. He was well aware, however, that, undertaken, as it frequently was, in the middle of the night, in a tenement house, by the light of a tallow candle or a kerosene lamp, and with such assistance as one could obtain under those circumstances, it was an operation which almost all surgeons approached with some sense of misgiving, especially as it was usually called for in the case of a young child having a short, thick neck and a deep trachea. These difficulties, however, were not so great but that they might all be surmounted when they were taken in hand by a man who understood anything of surgery, and had a cool head and a steady hand. The incision itself was

certainly a very simple one. The veins of the neck, if wounded, frequently bled profusely, and, if the operator was impressed with the hæmorrhage which was going on, and undertook to stop it entirely, as was inculcated by many authorities, before opening the trachea, he would probably have a job which would occupy the remainder of the night. If the case was not urgent, it might be proper to stop some of the hæmorrhage, even supposing it to be simply venous. Arterial hæmorrhage, if the incision was made properly, was seldom a troublesome complication in his experience. If, on the other hand, the case was one of emergency, where the great object was to make an opening into the trachea as quickly as possible, his custom was always to ignore this venous hæmorrhage, and cut into the trachea, feeling very certain, as the reader of the paper had stated, that hæmorrhage would usually stop as soon as the trachea was opened and the tube introduced. As to the entrance of blood into the trachea, he had regarded it as a matter of no special importance. It had, on the contrary, seemed to him sometimes to be the very thing which was needed to stimulate violent expulsive efforts, which would rid the trachea not only of the blood, but also of a quantity of mucus. On the adult he regarded tracheotomy as one of the simplest operations in surgery. In the young child it was much facilitated by placing under the back of the neck a common wine-bottle wrapped in a napkin, allowing the head to hang over it so as to render the trachea as superficial and prominent as possible. With regard to the isthmus of the thyroid gland, in operating in urgent cases, in which saving time was the great element, he would be inclined to ignore it altogether, cutting through it with the knife. If time was not an important element, and the gland was in the way and contained a large vessel, he would, of course, take the precaution to surround it with a ligature at each side and divide it between them, as had been indicated by Dr. Winters. As to the time when tracheotomy should be performed, he thought that, in order to be of much service, it should be done early. He did not think that the operation itself was in any sense a cause of death in membranous croup or diphtheria of the larynx. He was so strongly convinced of the importance of the operation that, if it was indicated, and no surgeon was at hand, he would perform it upon himself with a pocket-knife, and the aid of a hand-mirror.

Dr. A. JACOBI said that much had been written upon the subject by different writers, and Dr. Winters doubtless had recognized that it would be impossible to cover the entire ground in a single paper; that being the case, Dr. Jacobi would limit his remarks to some points brought out in the paper, and would not try to discuss the entire subject. The author had quoted extensively from European writers, both ancient and modern, with the principal object of showing that tracheotomy was not a dangerous operation, while but very limited reference had been made to American writers, some of whom, as Dr. Day, Dr. Hadden, Dr. Ripley, and others, had written papers containing much useful information upon this subject. With regard to the dangers of tracheotomy, he thought the principal one was a bungling operation, and by that he meant a bloody operation. Hæmorrhage was often due to the operator trying to get through with the operation as soon as possible. Tracheotomy should be performed deliberately, and the isthmus should not be cut through if the operator had as much as two or three minutes' time to spare. Many years ago he had lost a patient from hæmorrhage by cutting directly through the isthmus into the trachea. The child did not cough up all the blood which had been allowed to enter the trachea; even in a vigorous patient some of the fluid would be expelled ten, fifteen, or twenty minutes after the operation, and perhaps some of it would never be thrown up. Blood in the bronchi would have the same influ-

ence which so much viscid mucus would have, namely, to prevent the passage of air into the air-cells, which would cause them to contract and the blood-vessels to dilate, producing congestion and broncho-pneumonia. Another cause of danger was failure to administer chloroform. He preferred chloroform to ether because the child could be brought more quickly under its influence. He knew of cases in which babies had died from struggling in the arms of the nurse, who had taken them out of bed to make a simple nasal injection.

At what period in croup should the operation be performed? He was certainly of the opinion that after a diagnosis had been made we ought not to wait. He would not limit the operation to cases of membranous croup, but would also resort to it in those cases of laryngitis accompanied by stenosis of a congestive and oedematous type. He objected to dividing croup into stages in these cases, inasmuch as in some instances the operation was indicated quite early in the disease. He would operate in any case in which there was considerable laryngeal stenosis, recession about the supra- and infra-clavicular and ensiform regions, particularly if these symptoms increased in the morning; and, if the pulse was becoming frequent and irregular, he would say it was high time to operate. He would not ask in such a case whether there was membranous obstruction. Could we do anything in cases in which there was constitutional diphtheria, or diphtheritic sepsis? He would reply, Most decidedly. He would operate in these cases particularly, because as soon as the trachea was opened the child would cease to breathe the poisonous and fetid odors coming from the larynx and the nose.

Dr. Jacobi then directed attention to the use of bichloride of mercury for the prevention of the necessity of tracheotomy in croup. As to the causes of death after tracheotomy, they might be the same as those which would have caused a fatal result had the operation not been performed, but the principal causes of death after the operation were broncho-pneumonia, œdema of the lungs, and descent of the diphtheritic process.

Dr. J. LEWIS SMITH said that the older the child, other things being equal, the less the danger after tracheotomy. It seemed to him that there were two conditions in which tracheotomy was specially dangerous, one of which was that in which the patient was nearly moribund, and the surgeon was induced to operate hastily without due precautions against hæmorrhage. He thought that in the city, where assistance could always be had, the physician should not undertake the operation alone; but assistance might not always be accessible in the country. He fully agreed with Dr. Jacobi that the degree of laryngeal stenosis, and not necessarily the presence of pseudo-membrane in the larynx, should govern us in performing the operation. He would divide cases of membranous croup into two classes as based upon the necessity for an early or a later operation. If the laryngeal pseudo-membrane in diphtheria developed early it would be found to form more rapidly than if it developed, say, at the end of a week, and tracheotomy should be performed immediately; but in the other class of cases the membrane developed more slowly, and there he would try to prevent the necessity for tracheotomy by first using alkaline inhalations, or inhalations of trypsin, and by the internal administration of mercurials. *Tubage* had been employed with some success in the New York Foundling Asylum.

Dr. J. H. RIPLEY said that the author's ideas regarding the dangers of the operation, its difficulties, and its consequences, especially the consequences of a late operation, were all opposed to his own views. The question was not whether tracheotomy was a difficult or dangerous operation, but whether tracheotomy in young children for croup was a difficult and a dangerous operation. So far as the operation of tracheotomy in general was concerned, Dr. Ripley would say that it was neither very diffi-

cult nor very dangerous. The danger consisted, first, in the condition of the child, and, second, in the necessity for doing the operation within a given time. Dr. Winters, he believed, had touched upon only one danger, namely, hemorrhage. Dr. Ripley did not regard hemorrhage as the most common cause of death. We had to deal with children suffering from systemic poisoning and stenosis of the larynx, with the cellular tissue of the neck infiltrated with the products of inflammation, sometimes swollen out even with the chin, and, in order to get at the trachea, we had to cut down perhaps two inches, which required a good deal of time and a good deal of care, and, before the operation was completed, the child was liable to die of syncope; if the stenosis was great, and chloroform was given, the child was liable to die of apnoea; if chloroform was not given, the child would die from struggling. He was willing to go with the small minority, which included such names as Holmes, Gross, and Billroth, and say that he regarded the operation as dangerous. He had performed tracheotomy about one hundred and ten times, and had seen it done by other men about fifty times. He had witnessed all kinds of complications, and thought he had been the means of saving several lives by being present when inexperienced persons were operating. He had known ten deaths occur on the operating-table, the operations being performed by seven men, four of whom were careful and experienced surgeons. He knew of one instance in which the operator plunged the knife into the spinal column, in another it was plunged into the oesophagus, and in a third it was plunged quite through the trachea at one side of the median line. Dr. Winters had advocated early operations, but, as Dr. Ripley had before said, the man who operated early would have the best success, not for the reasons given by the author, however, but for the reason that unnecessary operations were those which were, as a rule, done early. We often had to watch the case closely for two or three days before a differential diagnosis could be made. It was true, as Dr. Jacobi had said, that there were a few cases in which it was necessary to do tracheotomy for stenosis occurring in the course of laryngitis. There were also certain cases of croup which would recover without treatment, and hence it was that there had been so many specifics for this disease. If late operations were the cause of death, then the causes of death must be those which Dr. Winters had spoken of—pneumonia, extensive bronchitis, infiltration of the lungs and of the bronchi—but Dr. Ripley thought that, if any fact in scientific medicine could be demonstrated, it was that incomplete stenosis of the air-passages above the air-cells produced not congestion of the lungs, but anæmia. The air-vesicles were in a state of acute emphysema, and, if this was true, delayed operations would not prove dangerous on account of broncho-pneumonia which was liable to follow. The causes of death, according to his observations, were, extension of the membrane into the bronchi and consequent suffocation, nephritis and uræmia, and respiratory and cardiac paralysis. He did not know that carbonic-acid poisoning would cause an extension of the membrane into the bronchi.

Dr. WINTERS, in closing the discussion, said, with regard to danger from blood entering the tracheal wall during tracheotomy, that such danger could be absolutely avoided by properly performing the operation. The scalpel should be laid aside after the integument was cut, not to be used again until the tracheal cartilages had been laid bare by careful dissection with two pairs of forceps, dividing any tough bands with dull scissors. He thought the views of Dr. Jacobi regarding the dangers of blood entering the bronchi were those first advanced by Niemeyer many years ago, that they were not accepted by advanced pathologists at present, and that they were abandoned by Niemeyer himself before his death. If any blood entered the

trachea it should be removed, together with whatever mucus might be present. He had not supposed that there was any question of the propriety of using an anæsthetic in tracheotomy for croup, nor as to a choice between chloroform and ether. Another reason, in addition to those offered by Dr. Jacobi for preferring chloroform to ether, was, that the latter was irritating to the air-passages. As to bichloride of mercury, he did not believe that it could be introduced into the blood in sufficient quantity to act as a germicide or as an anti-fermentative. The only influence which it exerted was as a tonic, and for this purpose it would never supersede iron. He did not believe that any autopsy had ever tended to show that tracheotomy had caused an extension of the diphtheritic process into the lower air-passages, and, in those instances in which the membrane had been found in the bronchi after tracheotomy, death had taken place too soon for the membrane to have developed after the operation. As to *tubage* of the larynx, it had been mentioned by Hippocrates, and had been at one time resorted to considerably in France, but had been entirely abandoned. Deaths on the operating-table were due either to delay or to carelessness. Dr. Ripley's statement that stenosis of the air-passages above the air-cells would not produce congestion, with its results, would not bear examination. Any one familiar with the physiology of the circulation knew that as soon as there was embarrassment of the respiratory act there was embarrassment of the circulation in the lungs, which caused damming back of blood upon the heart; with lack of aspiration-force from inspiration there was stagnation of the blood in the blood-vessels, and post-mortem examinations in croup showed passive congestion, the accumulation of mucus in the bronchi, pulmonary collapse, and, a little later, congestion of the lungs, pulmonary oedema, and the changes of broncho-pneumonia. Dr. Ripley had also spoken of croup being analogous to asthma and emphysema, but they were not analogous conditions at all. He had found but a single case recorded in which it was maintained that there existed a certain amount of emphysema the result of laryngeal obstruction in croup, and in that case it would appear the autopsy had not been made with care.

Dr. LOUIS ELSEBERG wished to say that Professor Gross had only taught that tracheotomy under the circumstances in which it was sometimes necessary to perform it, and not the ideal operation, was not always free from danger. He heartily coincided with the general views expressed in Dr. Winters's paper.

CLINICAL SOCIETY OF THE

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Meeting of November 22, 1884.

Dr. WILLIAM A. HAMMOND in the chair.

[From notes furnished by the Executive Committee.]

Functional Dyspepsia was the subject of discussion for the evening. Dr. A. H. SMITH spoke as follows:

In opening this discussion you will not expect me to give a lecture on dyspepsia. An attempt to do so would occupy the whole evening. Besides, the object of a discussion such as this is to bring out the personal views of the speakers, based upon their personal experience and observation. You will pardon me, therefore, if I do not take up the subject in regular order, but simply present such points as have impressed themselves most strongly upon my own mind, and I hope that those who follow will pursue a similar course, so that we may have as the result of this discussion the personal views of the members rather than citations of authorities. If we follow the successive steps of digestion, and imagine an aberration of the process at

each, it is easy to see that we may picture to ourselves as many forms of dyspepsia as there are organs employed in digestion. But this method is more readily followed in the library than in the consulting-room, and has more the flavor of *a priori* theoretical speculation than of clinical observation. Indeed, I question whether, setting organic disease aside, the functional disturbances are so limited to single organs that we can speak with any precision of gastric, hepatic, duodenal, pancreatic dyspepsia, etc. Practically we have two principal forms of dyspepsia, one for which the habits of eating are responsible, and another in which the digestive organs are really at fault. Thousands of dyspeptics suffer because they will persist in eating improper food, or food improperly prepared, or in eating too much, or too rapidly, or when the system is not in a condition favorable to digestion. In these cases there is no actual disease: the organs simply refuse to go beyond their normal function. But the continued operation of this cause will ultimately so derange the whole system as to result in the second form of dyspepsia, in which the legitimate duty of the digestive organs can no longer be performed.

The facts concerning the first form are so familiar that it is not necessary to dwell upon them. When the patient will learn to eat moderately and slowly of plain food properly prepared, and not to incur excessive fatigue during digestion, he will be practically cured. The second form, however, presents to us a somewhat complex problem, the key to which, I think, is to be found in the early establishment of a "vicious circle." The digestive organs hold a peculiar position in the economy. It is through them that the whole system receives its nourishment, and a failure on their part brings about a derangement of every other function to a greater or less extent. At the same time, as a part of the general system, the digestive organs are dependent upon the thoroughness of their own work for their own support and for the means of carrying on their own function. They can no more elaborate normal and efficient digestive fluids from impoverished blood than the nervous or the muscular system can do efficient work when suffering from a lack of proper nourishment. But the penalty for not properly elaborating such fluids is a further deterioration of the blood from which they are to be elaborated, and thus a vicious circle is at once formed. Indigestion produces imperfect nutrition; imperfect nutrition aggravates indigestion. This circle once established, the unaided powers of nature may be unable to break it. But if we can by any means do artificially some part of the duty which belongs to the digestive organs, or if, on the other hand, we can improve the quality of the blood without calling upon the digestive organs, we may so far break in upon the circle that nature can do the rest. Our efforts in the first direction take the form of supplying artificially the fluids and ferments required in digestion. Thus, we give pepsin* and hydrochloric acid to represent the gastric juice, and pancreatin and diastase to supply the deficiencies of the pancreas, etc. In the other direction, that of improving the quality of the blood without calling upon digestion, we act by means of nutritive enemata, or in extreme cases by transfusion. The efficiency of the first of these measures will surprise those not familiar with its use. A few injections of nutritive material into the bowel will often give an astonishing impetus to stomach digestion and enable it to regain its lost ground and thereafter to keep abreast of its work.

It is not to be forgotten, however, that digestion has a rival

force with which it has always to contend, viz., fermentation. So long as the digestive fluids are present in normal quantities and of proper quality, fermentation is kept in abeyance. But, the moment there is a failure in either of these respects, the vital process is mixed up with the chemical one, and fermentation products, which rightly have no place in the digestive tract, make their appearance, to delay digestion and to distress the patient. Slow digestion, from whatever cause, is certain to have this result. Hence, in these cases our efforts should be to hasten digestion, first, by appropriate hygienic means, and, secondly, by the use of artificial digestive agents. The action of these may be aided by certain medicines which have been found to act as digestive stimulants, such as the bitter tonics, which probably act through the nervous system. Direct stimulation of the gastric mucous membrane seems to favor digestion in some cases by inviting more blood to the glandular structures. Hence, the use of condiments or of a small quantity of alcohol with the meals is sometimes indicated. Some of the benefit which is unquestionably derived from drinking hot water may be explained in this way. Hot water is also useful in a class of cases in which there is gastric catarrh, and the inner surface of the stomach is coated with a tenacious mucus, which prevents the necessary contact of the ingesta with the mucous membrane. In these cases *lavage* sometimes gives excellent results. But, at the same time that we are hastening digestion, we may delay fermentation. A great many agents are used for this purpose, but the most convenient and efficient are, in my experience, boric and salicylic acids. Sodium salicylate is readily decomposed by the acids in the stomach, and its acid rendered active as an acid ferment. It has the advantage over the uncombined acid of being less irritating and more readily taken, and in acid conditions of the stomach the alkaline base is useful. Carbolic acid in small doses will act well, but has the disadvantages of being very disagreeable to many patients and of occasionally producing poisonous effects.

Dyspeptic patients are apt to drop one article of diet after another on account of some fancied disagreement with the stomach, until at last the bill of fare is reduced to a very limited number of articles, and these, very likely, such as the patient does not relish. In most cases it will be found that many articles have been discarded on very insufficient grounds, and may be restored to the diet list with great advantage to the patient. Often it will happen that a fair meal, even if almost forced down, will be followed by a better appetite at the next meal-time, the glands and the stomach having received in the mean time the benefit of being more fully nourished. Thus, while one class of dyspeptics should be directed to eat less, another class should be urged to eat more. A celebrated doctor of divinity, in this city, who was the victim of dyspepsia during his early life, says that he cured himself by "bullying his stomach," and there can be no doubt that a little discipline of this kind may often be of use. Out-door exercise is essential in every case, and, if it can be had, will often supersede the necessity for other treatment. Who ever knew a dyspeptic letter-carrier? Dyspepsia is more likely to receive too much rather than too little treatment. Encouraging the patient to eat a variety of food and to be much in the open air, with such occasional assistance from drugs as may be called for by the special indications, will generally effect a cure. Very obstinate cases are likely to have an organic lesion at the bottom, often atrophy of the gastric tubules.

Dr. STEPHEN S. BURT said: The near relation that exists between the stomach and the heart naturally suggests itself in connection with this discussion. For it is a matter of daily observation that sufferers from dyspepsia almost invariably refer to the heart as the cause of their trouble. This is so commonly

* Pepsin, to be of appreciable service, should be given in large doses. When we consider the great quantity of gastric juice that is secreted daily, and that nearly two per cent. of this is pepsin, the futility of five-grain doses is apparent.

the case that, when a patient complains of pain about the heart, palpitation, shortness of breath, and heartburn, followed by the assertion that he has heart disease, it is quite safe to assure him that such is not the case, provided he has not already been told by a competent examiner that he has organic disease of the heart. His shortness of breath will be found, upon further questioning, to be due to the difficulty he has in taking a deep inspiration, which is lessened rather than increased by exercise. The pyrosis, justifying its common name, heartburn, will very likely have caused apprehension also by directing his attention to the wrong viscera. All these symptoms can be removed by treatment directed to the stomach and to the intestines. But a patient with dyspepsia will not receive justice at the hands of his physician if a chemical examination of his urine and a physical exploration of his heart are neglected. For, while complaint is made of the heart in cases of simple dyspepsia, it may not be so well known that indigestion with flatulence of the stomach and of the intestines is one of the early results of an alteration in the blood and its circulation, not only in disease of the kidneys, but also in organic lesions of the heart. Long before there is any evidence of a compensation of the heart muscle, begins the venous congestion, which, among other ways, manifests itself by disordered digestion. And it is to this especially that I would direct attention, as treatment of a dyspepsia may prove unavailing if such a cause exists unrecognized; but, if it is known, on the other hand, an addition of from five to ten minims of the tincture of digitalis to an otherwise properly selected mixture for dyspepsia will result most satisfactorily.

Dr. W. H. PORTER stated that, of a thousand patients treated in his department of the school, fifty having been diagnosed as having dyspepsia, only four of the fifty had pronounced gastric symptoms. A large number had hepatic symptoms, headache, vertigo, chronic constipation, clay-colored stools, which, to him, would indicate hepatic indigestion as the primary cause of the dyspepsia. The speaker thought that, excepting in dyspepsia from improper food, the stomach itself was seldom primarily at fault. In sixty per cent. of these fifty cases there was an acquired or inherited specific taint. He improved these patients by remedying the constipation and treating the constitutional troubles. The speaker was acquainted with a gentleman who had been a dyspeptic for ten or fifteen years, who had learned to use the stomach-tube himself, and washed out his stomach whenever anything disagreed with him. At the end of six months of this treatment he was well.

Dr. M. P. JACOBI had used irrigation in two cases with very different results.

CASE I was that of a woman of fifty-five years, who had suffered from dyspepsia for eighteen years, and was much emaciated. By the carbonic-acid test, effected by giving separately the components of a seidlitz powder, so that the gas should be liberated in the stomach, this was found markedly dilated, extending below the umbilicus. This patient was able to receive into her stomach twenty-eight ounces of warm water, plain or alkaline, without discomfort. Vomiting was never excited by it, but the fluid was withdrawn by the pump, bringing with it a varying amount of viscid mucus. When plain water was used the entire amount injected was returned; but, with alkaline injections, from one to six ounces were always retained, as if they had been rapidly absorbed. The treatment, during steady application for a month, had thus far effected no marked change in the condition of the patient.

CASE II was that of a younger woman, about forty-eight. Her dyspepsia dated back only seven years, but dilatation of the stomach was demonstrated to exist. The patient did not suffer constantly, like the first one, but was subject to crises, which almost resembled the gastric crises of locomotor ataxia. In these she would vomit incessantly for two days, suffering at the same time from some epigastric pain, headache, and fever. In May this patient was restricted almost entirely to

liquid diet, using Leube's meat solution. She also used milk with Mellin's food and rusk. During the summer she was in quite good health, but in the autumn the crises of acute gastric catarrh reappeared. Toward the close of one of these crises, but while the digestion was still entirely disordered, irrigation was resorted to for the first time. There was great difficulty in introducing the tube, on account of the spasm of the pharynx, and, after a few ounces of water had been thrown into the stomach, it would be immediately ejected through the tube. The fluid was never either siphoned or pumped out, but always vomited in this way. This circumstance indicated a degree of irritability of the stomach which contrasted markedly with the atony of the first case, in which the mucosa was probably much atrophied. Notwithstanding the unpleasantness of the operation, the pain and discomfort were at once decidedly relieved. The washing was performed three times, at intervals of three days, and by this time the patient was feeling so well that the treatment was interrupted. Two weeks later she had continued to be perfectly well, and had commenced the use of solid food. She had since (about a month) remained quite free from the attacks and from the less acute gastric distress, which usually occupied the intervals. Irrigation of the colon was practiced in this case, by means of large cold-water enemata (two quarts), which the patient administered to herself on the days alternating with those of stomach washing. Not only was the constipation relieved by this, but the patient was emphatic in asserting the immediate sensations of *bien être* which followed their use.

The CHAIRMAN asked whether there was any microscopical evidence of sarcinæ in the vomited matter in the second case.

Dr. JACOBI said that the vomited matter had not been examined microscopically, but that there had been no hot vomiting characteristic of "water-brash," nor other symptoms to suggest this particular form of fermentation. Fermentation of some kind, however, unquestionably existed.

Dr. G. H. ELLIOTT said that in caries of the spine dyspeptic symptoms were not uncommon. Many children suffering from the disease had large, flabby abdomens, and their stomach and intestines were distended with gas. He considered the functional derangement of the gastro-intestinal tract due largely to the atonic condition of the muscular coat, the latter partaking of that lax condition which was present throughout the entire voluntary muscular system. The intestinal symptoms in caries of the spine often obscured an early diagnosis. He regarded functional disease of the gastro-intestinal tract as different from functional disease of other organs. In many organs functional maladies might exist a long time without producing a decided lesion, but functional disease of the alimentary tract could not long exist without producing a serious lesion—the great distensibility incident to the products of indigested food produced atrophy of the muscular coat and the gland structure. The speaker had met with an accident in washing out the stomach of a man who had the symptoms of ordinary chronic gastritis. There was no vomiting after taking food, no cachexia, no pain, and no tumor was detected by palpation, yet, on introducing the tube, the man suddenly died, and, at the autopsy, the tube was shown to have ruptured a vessel in a carcinomatous growth.

Dr. W. M. LESZNSKY considered strong tea, from its astringency, a frequent cause of dyspepsia in women.

Dr. W. O. MOORE related a case in which dyspepsia was always induced by overwork. In this case relief was afforded by galvanization of the pneumogastric nerves directly after a meal.

The CHAIRMAN said that the brain resembled a steam-engine of which the power was hired out to a number of individuals, one of whom might be deprived of his due share of the power from over-use by somebody else. The stomach, in Dr. Moore's case, had probably suffered in this way. There were some people who, no matter how little their brain-force might be, would try to use it to excess in their undertakings, and dyspepsia was one of the results. To cure this kind of dyspepsia, the most

essential condition was rest for the brain, or rather recreation. The theatre was a very good remedy, as it substituted for other brain-work the exercise of the perceptive faculties, which required less expenditure of nerve-force. The speaker gave in these cases as an anti-fermentative, glycerin, a half-ounce after each meal, with pepsin in large doses. Fairchild's pepsin was recommended, as it contained neither sugar nor starch. A few drops of the diluted hydrochloric acid might be added to this mixture. For the pain of dyspepsia, which might be so aggravating as to destroy all pleasure in life, the speaker had used the ice bladder to the stomach with immediate relief. It was supposed to act in a reflex manner, as sufficient time for cooling did not elapse. Dyspeptics should use principally animal food, which should not be overcooked. From eight to ten tumblersful of water might be beneficially taken with each meal. Iced water was objectionable, as was also the very hot water recently advocated, and for the same reason. Skimmed-milk diet was useful in cases of absolute absence of digestive power. A recent case of dyspepsia, in which the patient suffered from convulsive seizures, epileptic in character, was cured in this way. A board bill of fifteen dollars a day was reduced to a bill of thirty cents a day, and since commencing the treatment the patient has had no other attack.

Dr. A. H. SMITH closed the discussion. He considered that the Chairman had treated the stomach with disrespect. The engine would be of no use if there were not a coal-pit behind. The stomach was the coal-pit for the brain. Great thinkers had, as a rule, great digestive powers.

Acute Diffuse Nephritis following Intestinal Catarrh, in an Infant.—Clinical histories being in order, Dr. S. J. McNUTT related the history of a case of dyspepsia following intestinal catarrh, complicated with nephritis, in a child two months and a half old that had been brought to the Children's Clinic October 18th, with the history of having had diarrhoea for three weeks, and at one time from fifteen to twenty passages daily. It had never been fed on any other food than breast-milk. The evacuations were green and offensive, and contained pus. The child was irritable and started at a noise. The anterior fontanelle was slightly bulging, and the child cried when it was pressed upon. The temperature was 101° F., and the pulse rapid and compressible. Half a teaspoonful of castor-oil mixture was ordered to be given after each passage, and on the second day the temperature was 99° , and the pulse 120. The patient had slept, and the passages had been reduced to one a day, but they were full of fine flocculent curds. She was given half a teaspoonful of the syrup of the lactophosphates three times a day, before nursing, but the character of the stools did not improve, although the use of astringents, alkalies, and carminatives was kept up.

On the 26th she was reported as passing but little urine; there was restlessness, the pupils were contracted, and the eyes rolled up, the temperature and pulse were normal, and she was having four passages daily. About an ounce and a half of urine was withdrawn with a catheter, and it had the appearance of moistened corn-meal. Dr. Outerbridge found that its specific gravity was 1.016, that the sediment was about one fifth of the whole amount, and that albumin was plentiful, with a few lymphoid cells and small hyaline, epithelial, and granular casts. Two days later the child had convulsions, and, in spite of appropriate treatment, died in twelve hours. An autopsy could not be obtained, but, even without it, the evidence of acute diffuse nephritis was absolute.

Dr. McNUTT remarked that the association of intestinal catarrh with nephritis was recognized by Eustace Smith ("Disease in Children," 1884, p. 80) and by Hensch ("Vorlesungen über Kinderkrankheiten"), and that J. Lewis Smith ("Diseases of

Children," 1876, p. 619) said of the intestinal inflammation of infancy that uræmia might be the cause of death in certain cases. Hensch quoted Trietz as having observed intestinal troubles as an accompaniment of nephritis, and accounted for it by the irritation caused by urea in the blood. Eustace Smith, on the contrary, quoted Kjellberg as considering the nephritis as a complication of the catarrh. Kjellberg stated that in one hundred and forty-three cases of fatal intestinal catarrh he had found kidney disease in sixty-seven, and these figures were calculated to excite apprehension of kidney trouble in cases of intestinal catarrh, especially when cerebral symptoms appeared, the latter being commonly considered to be due to the reflected irritation from the canal, or to exhaustion from the diarrhoea, as in spurious hydrocephalus. According to Eustace Smith, Parrot had suggested that spurious hydrocephalus might even be caused by uræmic poisoning from deficient renal secretion. The symptoms of brain trouble in these cases were so similar to those of uræmia that the possibility of the latter should always be considered, and examinations of the urine should be a matter of routine in cases of intestinal catarrh. It was known that, normally, the proportion of solids in a child's urine was double that in an adult's, and in intestinal catarrh the urine was still more concentrated on account of the watery drain through the bowel. It was possible that this concentrated urine might in itself be sufficiently irritating to cause the nephritis. In the case that had been related, however, the great scantiness of the urine did not occur until the diarrhoea had been checked; it appeared as the result of the nephritis rather than as its cause. But there was almost complete indigestion at that time, and it was suggested that the circulation of the products of fermentation might have been the origin of the kidney complication. The syrup of the lactophosphates was given to combat this lack of digestive power, for it was known that pepsin was of little use in the dyspepsia of infants, from the fact that it did not aid the digestion of unaltered casein. According to the researches of Hammerston (Hermann's "Handbuch der Physiologie," vol. i, p. 49), the milk was first coagulated by a peculiar ferment, active only in the presence of the earthy phosphates, and was then attacked by the pepsin. The milk of anæmic women being deficient in phosphates, the syrup of the lactophosphates was given to supply the lack; although in this case it was given too late, in the majority of cases of simple functional dyspepsia great improvement followed its use.

Dermatitis following the Use of a Toilet Preparation of Heliotrope.—Dr. W. M. LESZINSKY related the history of the case of a man who bathed his lower lip, chin, and brows with Lubin's "triple extract of heliotrope," and immediately felt a slight stinging sensation, which gradually disappeared during the evening. The next morning the parts were red and slightly irritable, and toward evening so severe a dermatitis had developed that both eyes were closed, the face was swollen, and the features were distorted beyond recognition. These effects were confined strictly to the parts to which the perfume had been applied. The pain became so severe that the patient could not sleep, but the inflammation gradually subsided in the course of four days, passing through successive stages of eczema and furunculosis. The case was treated like one of dermatitis venenata, or rhus poisoning. Equal parts of liquor plumbi subacetatis dilutus and lime-water seemed to increase the discomfort and produced intolerable itching; the greatest relief was obtained by the almost continuous application of cloths wet with fluid extract of hamamelis. The patient had never before had dermatitis, although he was accustomed to the use of bay rum. An acid resinous principle had been found in the specimen of heliotrope extract that was used, but nothing else to account for the result.

Dr. A. H. SMITH had seen a similar dermatitis produced by the application of tincture of arnica, diluted with water, to the knee, the eruption resembling erysipelas, and extending as far as the arnica had been applied. It was also to be seen in spots on the face and breast, where the patient had applied his fingers wet with the fluid. The arnica flower was known to be infested sometimes by an insect that had the properties of the Spanish fly, and the irritant principle was soluble in alcohol, but not in water. Accordingly, the infusion of arnica had never been known to give rise to the symptoms. Possibly the heliotrope flower was at times infested in the same way.

The CHAIRMAN thought this supposition was unnecessary, and suggested that an idiosyncrasy was more probable. He alluded to a case in which like symptoms were always produced by turpentine.

A Pocket Armamentarium against Pain was shown by Dr. DANA. It was a small case containing four phials: one for a two-per-cent. solution of Duquesnel's aconitine in oleic acid, to be rubbed over neuralgic points; another for a fifty-per-cent. alcoholic solution of menthol, to be applied in like manner; a third for bisulphide of carbon, this phial having a wide mouth, so that it could be inverted over the seat of pain and the diffusion of the disagreeable odor of the drug prevented; and a fourth for chloroform, to be applied in the same way. A small spray-apparatus, with a phial of ether, might be added.

An Electric Light for Examinations was shown by Dr. W. O. MOORE. It was designed for use in examinations of the mouth and throat. The battery consisted of three cells in a portable box. The handle of the instrument, made of hard rubber, contained a resistance coil, and at the end there was an incandescent lamp, about half an inch in diameter, protected by hard rubber on one side, so that the mouth should not be burned. A laryngeal mirror could be arranged on the handle. The instrument was made by the Excelsior Manufacturing Company, of New York.

A Dynamometer, for testing the flexors of the hand, was shown by Dr. GRÈME M. HAMMOND. It consisted of an elliptical spring, to one end of which a dial-plate was attached. At the center of the dial two hands revolved on an axis, one superimposed upon the other in such a way that, when the sides of the spring were compressed, the upper hand made the circuit of the dial, carrying the lower hand with it, and the latter remained stationary at the farthest point reached, while the former returned to the starting-point when the spring was relaxed. The instrument was said to have two advantages: 1. The dial being outside the spring, the movements of the hands could be watched while the instrument remained within the patient's grasp, so that the observer could note the ability to sustain steady muscular contraction or a tremulous wave of contraction. 2. The dial being larger and the hands longer than in the old form of the instrument, very slight degrees of pressure were more readily indicated.

Miscellany.

THERAPEUTICAL NOTES.

Terpin.—The "Lyon médical" credits M. Fournie with the therapeutic application of this substance, the formula of which is given as $C_{10}H_{16}O_3$. According to the method suggested by Deville, it is prepared as follows:

Oil of turpentine.....	4 litres;
Nitric acid.....	1 litre;
Alcohol (80 per cent.).....	3 litres.

Mix thoroughly, and expose to the sun for six weeks. Transparent rhomboidal crystals are deposited, which are re-dissolved in alcohol. M. Fournie states that, if the mixture is distributed in several vessels, an exposure of only two or three days is required.

The alcoholic solution has been used, with good results, in bronchitis and chronic nephritis, in doses of from three to six grains. In bronchitis it acts as a stimulant expectorant, but, unlike turpentine, it increases instead of diminishing the bronchial secretion. In renal disease it shows decided diuretic powers from its direct action on the renal epithelium. It is to be used with caution in the latter cases, since large doses administered to animals have caused fatal hæmaturia.

The Effects of Anæsthetics on Drinkers.—M. Dubois, writing in the "Gazette des hôpitaux," says that, after observing the effects of chloroform upon alcoholic subjects, he was led to make a series of more exact experiments upon animals, as a result of which he draws the following practical deductions: Anæsthesia is induced more rapidly than usual when the patient is in a condition of acute alcoholism; a smaller quantity of chloroform is required; a larger proportion of fresh air is necessary in order to avoid a fatal result.

Ichthyol in the Treatment of Eczema.—Dr. Sinclair ("British Medical Journal") has used this remedy with success in several cases, but he thinks that its local application is not free from danger. In one instance an infant four months old sank into a state of stupor two hours after its head and limbs had been rubbed with an ointment of one part of ichthyol to five parts of vaseline.

Mullein in the Treatment of Phthisis.—In the same journal Dr. Quinlan says that he has made extensive experiments with this herb, and believes it to be superior to cod-liver oil as a curative and weight-increasing agent in the "pretubercular" stage of phthisis. It also possesses valuable expectorant powers in the later stages of the disease. He gives it in the form of a decoction prepared with milk. The leaves of the "great mullein" (*Verbascum thapsus*) are the only ones that possess the peculiar virtue.

Intra-venous Injections in Cholera.—M. Hayem has reported to the *Académie de médecine* ("Union médicale") a series of twenty-three cases of cholera, occurring at the Hôpital Saint-Antoine, which had been treated with intra-venous injections of salt water. Twenty of the patients were cured. The following solution was used:

Chloride of sodium.....	gr. lxxv;
Sulphate of sodium.....	3 iiss.;
Distilled water.....	5 iij.

Filter and warm to 38° C. The amount to be injected varies from six to eight ounces in the adult. Twelve to fifteen minutes should be taken for the operation. M. Hayem stated that he had himself employed this method of treatment in two hundred cases, with the result that twenty patients were cured and five improved. He had noticed the following phenomena after the injections: first, an intense rigor; then a gradual return of the surface heat, followed by a cessation of the cramps, repose, and often sleep. After this sudden reaction, the patient at once began to convalesce. In one instance the cure was perfect in two days. He thought that saline injections should not be regarded as a *dernier ressort*, but that they should be tried at the beginning of the algid stage.

Tartenson's Formula for Choleraic Diarrhœa is given as follows in the same journal:

Tincture of <i>Chelidonium majus</i>	℥ j;
Julep gommeux*.....	3 v.

Dose, a tablespoonful every two hours.

Gicquel's Anti-cholera Mixture, according to the same journal, is prepared as follows:

Extract of opium.....	2 grains;
Peppermint water,	
Distilled water,	
Syrup, each.....	10 fluidrachms;
Liquor ammonii acetatis.....	5 "

Dose, a tablespoonful every half-hour until two doses have been given, then a tablespoonful every hour or two, according to the nature

* An excipient consisting of gum arabic, syrup of marsh-mallow, and orange-flower water.

of the case. In the case of children the amounts of opium and acetate of ammonium are to be diminished.

Reuss's Tonic Pill, according to the same journal, is made as follows:

Arsenate of iron, gr. iijss.;
Extract of gentian,
Extract of calumba, each, gr. xxx.

Divide into forty-eight pills. In the case of persons of weak constitutions, where the development of tuberculosis is apprehended, one pill may be given at breakfast-time for eight successive days, after which an additional pill may be administered at dinner-time. Cod-liver oil and quinine, with counter-irritation by means of applications of tincture of iodine, should be resorted to in addition if there is any suspicion of dullness at the apices.

Tailed Men.—At a recent meeting of the Berlin Medical Society Professor Virchow read an interesting paper on this subject, in which he reviewed Redner's and Bartels's labors, and referred to some curious statistics by Dr. Umstein, the Surgeon-General of the Greek army. The latter had noticed so many cases of rudimentary caudal appendage among recruits presenting themselves for examination that he had drawn the inference that the Hellenic race was particularly prone to the deformity, and he had shown, by reference to the statues of satyrs, that the condition must have been noticed by the ancient Greeks. Virchow called attention to the fact that, although the natural tendency was to regard these sacral appendages as rudimentary tails, the argument was not sound unless it could be shown beyond doubt that the processes were really extensions of the vertebral column. Those cases, he said, in which the bony column was actually traced down into the tail had been reported by the older anatomists, and, therefore, were to be regarded with some distrust. Most of the caudal processes reported in recent times had been what he would characterize as "imperfect tails," consisting only of connective tissue, and perhaps they were simply of dermal origin. Redner, however, had not regarded this fact as militating against his theory. Virchow cited a case in which there was a peculiar growth of hair over a prominence in the sacral region, but, on close examination, it was found to be simply a spina bifida. "Consequently," he remarked, "we had here to do not with an atavistic, but with a pathological product."

Bartels said, at the same meeting, that we must distinguish carefully between tails which contained bones and those which did not. Among the former were to be classed what he called the atavistic tails, but he added that no undeniable example of the latter had yet been found. He thought that there were five varieties of the rudimentary caudal appendage in man: 1. The short stump, without bony contents, representing the remains of the foetal tail. 2. The "pig-tail," also boneless, arising from an actual increase in the size of the original foetal process. 3. The "swollen" tail, due to persistence of the prominence which remained after the disappearance of the embryonic tail (*Steisshöcker*). 4. The bony tail, which was due to hypertrophy of the sacral vertebrae rather than to an increase in their number. 5. "The still doubtful atavistic tail," in which there was an actual increase in the number of the vertebrae.

Cobra Venom.—Dr. Wolfenden, writing in the "Indian Medical Gazette," gives the result of some interesting experiments upon this subject. After reviewing those of other investigators, especially Wall and Weir Mitchell, he describes his own, which were undertaken with the object of throwing light upon the chemistry and the physiological action of cobra poison. The dried poison was used, which is soluble in water, but forms a cloudy solution on account of partial precipitation of the globulin. By boiling the fluid the proteids are coagulated, and, as the filtrate is found not to be poisonous, the venom must be incorporated with the proteids. The latter bodies may be separated into a globulin venom and a serum-albumin venom, and according as the one or the other of these is present in excess will the symptoms be chiefly of the paralytic or of the asphyxiating character. "Morphologically," he observes, "the glands secreting the poison resemble parotids, and the resemblance is still more striking from the occurrence of a diastatic ferment in the secretion, which was long ago spoken of as analogous to

pytalin. The venom is generally thought, physiologically, to be modified salivary secretion, consequently we should scarcely expect to find peptone present." Solutions containing each of these albumins were injected beneath the skin of rats, with varying results. The following general deductions are made: 1. In cobra poison there are two different venoms, cobra globulin venom, and cobra albumin venom. 2. The former is destroyed by a high temperature, but the latter is not affected. 3. The globulin venom poisons the respiratory center, producing no paralysis of muscles; the albumin venom does not affect the respiratory center, but produces marked and progressive motor paralysis. The statement is added that the bacteria, which are found in large numbers in cobra venom, have nothing to do with its activity.

Disinfecting the Sputa of Phthisis.—Dr. J. Sormani, Professor of Hygiene at the University of Pavia, gave some interesting details at the Hygienic Congress of the Hague concerning experiments made this year on one hundred and fifty Guinea-pigs with the sputa from phthisis. The object in each case was to ascertain what chemical or other methods would neutralize the bacillus, which it was previously ascertained existed in large numbers in the sputa. The results of these experiments were summarized in the following manner: 1. The bacilli of tuberculosis were generally very difficult to destroy; dryness, exposure to oxygen, putrefaction, and most disinfectants failed to produce any effect. 2. A temperature of 100° C. only killed the bacilli after at least five minutes of ebullition. 3. The artificial digestion of bacilli showed that they were the last of all living organisms to be destroyed by the gastric juices or chloridic acid. A very active digestion is necessary to kill this microbe. A healthy man may destroy the bacilli in his stomach, but an infant or an adult with his digestive faculties impaired would easily allow the germ to pass the stomach intact, and retain its virulence in the intestinal tube. This determined enteric ulcerations, etc. 4. The bacillus of tuberculosis can be preserved intact for a whole year when mixed with water. It is probable, though not proved, that it has retained its virulence during that time. Thus drinking water may become the means of propagating tuberculosis. It is probable that contaminated linen retains its virulence for five or six months. 5. Alcohol does not destroy the germ, and hard drinkers often suffer from tuberculosis. 6. Cod-liver oil, ozone, oxygenated preparations, and other similar remedies, have no effect in killing the bacillus, nor are benzoate of sodium, salicylate of sodium, sulphate of zinc and carbolic acid, iodide of silver, bromide of camphor, etc., of much greater use. They injure, perhaps, but do not absolutely destroy the bacillus—at least not in the doses that can be taken without danger. 7. A more decisive action may be attributed to creosote, eucalyptol, pure carbolic acid, the naphthols, and bichloride of mercury. 8. For disinfecting spittoons, carbolic acid solution at 5 per cent. is thought sufficient, and Dr. Sormani asserts that the breath never contains any bacillus. He also suggested that essences of turpentine or eucalyptol should be diffused in the houses as an agent for the destruction of this special germ.—*Lancet*.

An Appointment under the New State Civil-Service Rules has lately been made, the position being that of First Assistant Physician to the Hudson River State Hospital for the Insane, at Poughkeepsie. Thirteen candidates were examined by a very competent board, sitting in New York, and the successful candidate was Dr. Frederick Peterson, of Buffalo.

Bartholow's "Materia Medica and Therapeutics."—We understand that this standard work is to be translated into French.

Progress in Antiseptics.—It is reported that Esmarch now uses metal operating-tables at his clinic. All the instruments are said to be nickel-plated and to have metallic handles. By discarding wooden articles, the great surgeon hopes to diminish the risks of septic infection, says the "St. Petersburger med. Wochenschrift," from which the foregoing is taken.

Deaths from Anæsthesia.—In the "British Medical Journal" Jacob reports thirteen cases of death from anæsthetics in England during the year 1883, eleven of which were due to chloroform, one to a mixture of chloroform and ether, and one to nitrous oxide. The fact that the total is smaller than in previous years is ascribed to the general use of ether.

Original Communications.

LARYNGEAL SPASM.*

By LOUIS ELSBERG, A. M., M. D.,

PROFESSOR OF LARYNGOLOGY AND RHINOLOGY IN THE NEW YORK POLYCLINIC
AND IN DARTMOUTH MEDICAL COLLEGE.

MR. PRESIDENT AND FELLOW-MEMBERS: At our meeting in Boston, in a paper on the "Muscles of the Larynx and their Paralysis," and again, last year, in discussing Dr. Lefferts's description—under the very startling caption, "*New Facts in Laryngology*"—of two cases of so-called laryngeal vertigo or laryngeal epilepsy, I made a few remarks on spasm of the larynx. Now I call your attention to the same subject at the special request of our President. I desire, however, to apologize to you for my very imperfect manner of presenting it. I have had no opportunity of writing down what I am about to read until this very morning. If I can do no more, however, I may at least lead you to study, under one systematic head, some very interesting conditions which have been hitherto considered as anomalous and as more or less unrelated; and I promise you that, if I live, I will prepare a more elaborate essay on the subject before our next annual meeting.

Although laryngeal spasm has doubtless occurred in all times of history, our knowledge of it is comparatively recent. As to children, who are affected by it more frequently than adults, the first description seems to be only about two hundred years old; and, as to adults, there reigns much confusion concerning it at the present day. The affection is not properly appreciated even by throat specialists, and particular cases of it have been heretofore diagnosed as cases of paralysis of antagonistic muscles, or recorded, as even members of our own association have done, by such objectionable names as laryngeal chorea, laryngeal epilepsy, nervous cough, choked voice, aphonia spastica, etc.

DEFINITION AND CLASSIFICATION.—Laryngeal spasm is the spasmodic contraction of one or more of the laryngeal muscles. It may be unilateral (although I personally am not sure, at this moment, that I have ever observed it confined to one side) or bilateral. It may be simple and affect only one muscle or one group of muscles of the larynx, incompletely or totally; or it may be complicated, and in the latter case involve not only laryngeal muscles, but also the diaphragm, other respiratory muscles, and even other muscles of the body. It may occur either in the domain of the superior laryngeal nerve or in that of the inferior laryngeal nerve, or in both; and it may affect either the adductor or the abductor muscles. Its individual paroxysms may be induced by exercising a particular function of the larynx, or they may come on spontaneously while the patient is only quietly breathing. The special classification that I make is: I. Abductor Spasm; II. Adductor Spasm; and, 1. Deglutitory, 2. Inspiratory, 3. Expiratory (including 4. Phonatory) forms, these being (a) simple, or (b) complicated.

SYNONYMS.—So far as I remember at this moment, with the exception of Fraentzel and Cohen (and perhaps Hack), no author has hitherto described laryngeal *abductor* spasm, and all the synonyms that have been used for laryngeal spasm, or laryngospasmus, or laryngismus, or spasmus glottidis—and, indeed, these designations themselves—have been applied to *adductor* spasm only. These synonyms are laryngismus stridulus, laryngeal asthma, stridulous laryngitis, spasmodic laryngitis, pseudo-croup, spasmodic croup, nervous croup, cerebral croup, suffocative convulsion, internal convulsions, angina spastica, and angina stridulosa. As observed mainly in children, and for the same in either children or adults, and for various forms of the same: tetanus apnoicus infantum, intermittent asthma of children, clangor infantum, child-crowing, crowing inspiration, vocal asynergy, disordered co-ordination or perverse action of the laryngeal muscles, aphonia spastica, dysphonia spastica, spasmodic cough, nervous cough, hysterical cough, laryngeal chorea, laryngeal vertigo, etc.

ÆTIOLOGY.—It is well to distinguish between predisposing and exciting causes in the production of laryngeal spasm, and among predisposing causes morbidly increased irritability and reflex activity of the nervous system occupy the first place. It is mainly on this account that age exercises a very great influence upon the occurrence of the affection. Although I have seen several cases in infants a few days or weeks old, and from that age up to seventy years, it occurs most frequently after the fourth and before the twenty-fourth month of life. To regard it as exclusively a disease of childhood is erroneous; some forms of it, indeed, have been observed in adult age only, and the excitable condition of the nervous system, predisposing to convulsive muscular action on the one hand, and the small size of the rima glottidis and flexibility of the cartilaginous frame-work of the larynx on the other, sufficiently explain the frequency and gravity of laryngeal spasm in children. As to sex, boys are more frequently affected than girls, but adult women more frequently than men.

Hereditary influence has been looked upon as an efficient factor, but this acts probably only very indirectly. The physical organization of a child is very influential in the production of the disease. Children who are ill nourished and live in badly ventilated rooms are, above all others, subject to the disease. Among the upper classes, hand-fed children are most frequently attacked, while among the poor the affection is most common where the mother is in bad health, or continues to suckle for too long a time. Often the disease comes on at the time of weaning, by the use of farinaceous food which the child is unable to digest. Rhabditic conditions frequently accompany or cause a predisposition to spasm; indeed, according to some statistics, three fourths of the whole number of children affected are rickety. Various cerebral affections, especially hydrocephalus and microcephalus, predispose to the spasm. Enlargement of the thymus body, which at one time was supposed to be the only cause of infantile laryngismus, is occasionally present, but is probably never really causative; but pressure upon the laryngeal nerves in children or adults, whether proceeding from en-

* Read before the American Laryngological Association, May 14, 1884.

largement of the thyroid body, lymphatic glands, aneurysmal or other tumor in the neck or within the thorax, when not sufficient to cause paralysis, may produce spasm. In locomotor ataxia, hydrophobia, tetanus, epilepsy, and chorea, laryngeal spasm is apt to occur; and the hydra-headed neurosis, hysteria, must never be left out of sight as a very influential, predisposing, and occasionally even as an exciting, cause of laryngeal spasm. Injuries, foreign bodies (as a little milk during sucking of infants, or a little saliva, or in adults a drop or a crumb of some kind, getting into the larynx), or direct or reflex nervous irritation, may bring on laryngeal spasm. Spasms, more or less severe, are not uncommon in hyperæsthesia of the larynx, and especially in the over-sensitiveness of the mucous membrane sometimes persisting after the removal of inflammation or irritating conditions of the larynx, of tumors, etc. Paralytic conditions of one muscle or set of muscles sometimes excite spasm of associated or antagonistic muscles.

Among the exciting causes in children, catarrhal irritation of the respiratory mucous membrane is an important one, and it is on this account that infantile laryngismus is more frequent in the winter months, especially in March; gastric disturbances constitute another: indeed, one author (Flesch) seems to regard improper (and especially over-) feeding in infants as the only efficient cause; emotional excitements, such as fright, anger, or a crying spell, are sufficient to produce a paroxysm in a child subject or predisposed to laryngeal spasm. In adults, also, emotional causes and shocks of various kinds may act as exciting causes, aside from the exercise of a particular laryngeal function, which is a usual exciting circumstance. In one of my adult patients one of the worst attacks was brought on by being in a high swing; in another by being shampooed and having too much water poured on the head. I remember a young girl, from the northern part of this State, who was sent to me by Dr. Faneuil D. Weisse for treatment, about ten years ago, suffering from complicated expiratory adductor spasm, in whom a very severe paroxysm could be produced on touching with a probe her greatly enlarged and degenerated tonsils. Removing these and a catarrhal condition (which existed especially at the upper aperture of the larynx) completely cured the patient, in whom, however, some months later, chorea appeared, from which, as I afterward understood, she only very gradually recovered.

SYMPTOMS AND DIAGNOSIS.—The symptoms of laryngeal spasm differ entirely according to the set of muscles affected. In adductor spasm there is excessive approximation of the vocal bands, or in some other way closure of the laryngeal aperture; in abductor spasm there is insufficient closure of the rima glottidis.

I. Adductor Spasm.—Dr. Fraentzel has described a case of spasm of the abductors co-existing with paralysis of the adductors. The symptoms were absolute aphonia and absence of the slightest indication of laryngeal sound; even cough was entirely inaudible. The laryngoscope showed the vocal bands, during attempts to phonate and during forced expiration, in the completest inspiratory position. If I remember correctly, Dr. Cohen has exhibited before this association, at its first or second meeting, a similar case;

he has recorded four additional cases of apsithuria; but whether or not there existed abductor spasm in these I can not at this moment say. I have had under my care at least five (and it may be more) patients in whom I positively diagnosed spasm of the posterior crico-arytenoid muscle. In most of them—perhaps in all but one—there was also more or less adductor paralysis; but in one case, in which there was recurrent complete apsithuria (i. e., inability to whisper) and inability to make voluntarily any laryngeal sound whatever, and in which the laryngoscope showed the vocal bands in extreme inspiratory position, etherization, performed for diagnostic purposes, proved the integrity of the adductor laryngeal muscles. This patient could also at other times involuntarily make audible sounds; sometimes he could laugh and cough aloud, etc. The spasm relaxed at irregular intervals, and occasionally came on for a few minutes only, just when the patient desired most to talk.

II. Adductor Spasm.—The symptoms of adductor laryngeal spasm vary according to the number of affected muscles, the degree and the form. A laryngoscopic examination is not always possible; when successful, it reveals in some cases nothing abnormal or nothing characteristic; in other cases the image varies according to what particular muscle or muscles may be affected; thus isolated spasm of the lateral crico-arytenoid gives the same image as combined paralysis of the thyro-arytenoid and arytenoid muscles, spasm of all the adductors—gives an image somewhat similar to, but more varying than, that of paralysis of the abductors, etc. Diagnosis is sometimes rendered more difficult on account of the co-existence of spasm of one muscle with paralysis of another; but a correct conclusion can be arrived at by the careful consideration of the symptoms and the mirror-observation under varying circumstances.

1. In the simple deglutitory form of adductor laryngeal spasm, the act of swallowing itself may show nothing abnormal, but immediately after it is finished, with or without a little spasmodic cough, more or less suffocation supervenes. There may be so much narrowing of the rima glottidis that the patient may suddenly frantically grasp his throat, struggle for breath, become cyanotic in the face, and lose consciousness. All this lasts less than a minute, the patient regains consciousness, can breathe perfectly well, and, until the next attack, can swallow both solids and liquids freely, while after an irregular interval—sometimes an interval of days or weeks, and even months—the mere performance of the act of swallowing may bring on another paroxysm; but I have seen one very marked and unquestionable case of this kind, in which for nearly a week there was complete or total spasm of all the laryngeal adductor muscles *whenever* the patient swallowed, so that starvation stared her in the face. In other cases only the swallowing of solid, and in some the swallowing of a particular article or particular articles of food, brings on an attack. The dreaded infantile adductor spasm (usually complicated inspiratory spasm) occurs in some children, who are subject to it, on swallowing, during sucking, especially from a bottle. Cases are reported by Flesch in which the use of a nursing-bottle, and even a tablespoon, had to be given up

on this account, and food had to be administered with the smallest teaspoon to avoid the spasm.

2. In the simple inspiratory form there are more or less dyspnoea and strident noises with every inspiration, while expiration is normal, deglutition free, there is little or no cough, and the voice is unaffected. On etherizing or chloroforming the patient, and during natural sleep, the dyspnoea and stridor disappear, and the attacks often intermit for hours. The laryngoscope shows normal movements of the vocal bands during phonation and expiration, but, on attempted inspiration, the bands, instead of separating more widely when they are in the cadaveric position, approach each other with abrupt and oscillating jerks, sometimes being forcibly pushed against each other and held a moment together. In severe cases the violent and complete closure of the rima glottidis may last long enough to cause unconsciousness before the spasm relaxes. This is a condition which sometimes may be mistaken for paralysis of the posterior crico-arytenoid muscles, especially as it is occasionally combined with that affection; but it may exist without it, and then the abductor muscles may at times be seen to act perfectly. The differential diagnosis can readily be made unless there is such a thing as transitory paralysis as well as permanent spasm. Most of the cases of the heretofore so-called laryngeal vertigo are cases of inspiratory, some of them of deglutitory, adductor spasm.

3. In the simple phonatory form there are no symptoms unless the patient attempts to sound his voice. When he does so, the vocal bands quickly and forcibly approach each other and close the rima so completely that the voice is, as Dr. French, though not recognizing the precise condition, has well expressed it, "*choked.*" If the patient persists in the phonatory effort, severe dyspnoea, pain, and other cramps may ensue, and the ventricles of Morgagni may be so forcibly inflated that the ventricular folds appear swollen, *i. e.*, the two folds may be in contact with each other; but, if the patient ceases to try to phonate, all symptoms pass away almost immediately, and respiration becomes free. Sometimes the patient can stutter out a few words or sentences, sometimes he can not make a single sound. Sometimes the words that are pressed out are high and squeaky, sometimes they are husky and low and labored.

4. In the simple expiratory form the attack comes on if the patient attempts to whisper, as well as if he tries to talk or sing; or it may be that the attack comes on, as in a case of Nothnagel's, if the patient attempts to blow out a burning candle; as in a case of Voltolini's, if he coughs forcibly; or as in a case of Jouquièr's, if he laughs.

In cases of simple expiratory, including phonatory, spasm, one important point to be noticed is that the patient generally finds it easier to make vocal sounds on inspiration than on expiration, and may gradually fall into the habit of inspiratory phonation. This necessitates a puffing out of inspired air from time to time, which, together with the acoustic character and laboriousness of the patient's voice, are quite characteristic. As the laryngeal muscles under these circumstances are overworked, they become fatigued, and paresis, or even paralysis, of one or more of them ensues. Sometimes the order of occurrences is the reverse, *i. e.*,

sometimes paralysis and inspiratory phonation precede and cause the spasm.

In simple expiratory and phonatory spasm the laryngoscope reveals the spasmodic contraction of the adductor muscles, and the image seen varies with the muscle or muscles affected. The lateralis (lateral crico-arytenoid) is generally involved, also the inferior (thyro-arytenoid), with or without the transversus (arytenoid). In a case reported by Hack, the latter muscle was paralyzed, hence the otherwise forcibly closed rima showed a triangular opening posteriorly. Spasm of the anticus (thyro-cricoid) muscle is sometimes found combined with depression of the epiglottis, which depression persisting, even after the spasm may have yielded, leads, especially in children, to apnoea and death.

5. In the complicated expiratory form, the main symptom is a curious cough. Some authors have attempted to characterize this cough by its mode, others by its acoustic properties or by both.

a. As to its mode, it is of two kinds, being either (1) a paroxysmal cough, in which, as long as it lasts, hack follows hack in rather quick succession; or (2) a continuing cough, in which the hacks follow each other incessantly at regular intervals. In the first the hacks are sometimes exceedingly violent—from thirty to one hundred and more a minute—and during the paroxysm, which may last for a minute to a quarter of an hour, and even longer, the patient can not stop them. As a rule, the cough is dry, though frequently at the end of a paroxysm there is a little sputum expectorated. The paroxysms occur once or several times a day, usually at irregular, but sometimes at regular intervals; usually spontaneously, but sometimes induced by an external cause, especially emotional or physical excitement or exertion. They do not occur during sleep. In the second kind, the continuing cough, the hacks, not so severe as in the paroxysmal kind, observe a regular and sometimes a very complicated rhythm. The intervals vary from a number of seconds to several minutes, very seldom, however, being as much as half an hour. Like the paroxysmal, the continuing cough usually stops during sleep, though this is not so invariably the case with the latter; but, unlike the former, it can be controlled by the patient while talking, singing, yawning, or swallowing, or during a laryngoscopic examination. Except by such or similar functional exercise, the patient's will has little or no restraining influence; on the contrary, sometimes the hacks are aggravated when the patient tries to suppress them or pays special attention to them, the same effect being sometimes produced when the patient is conscious of being observed by others. Preceding, accompanying, alternating with, or following this kind of spasm, other spasmodic movements, especially of the facial muscles, and also other involuntary and incoordinate twitchings constituting chorea, are sometimes observed. It is this spasm or cough which has given rise to the diagnosis of "laryngeal chorea," a designation which I decidedly advise you never to use.

b. As to the acoustic properties of the cough of the complicated expiratory form of laryngeal adductor spasm, it must be stated that these often are peculiar. They resemble occasionally the barking or yelping of a dog, the quacking

of a duck, the lowing of cattle, or crowing, or are shrill, metallic, or croup-like. Usually the noise is quite loud, sometimes so extraordinarily loud that it can be heard at great distances, exceptionally so little loud that it can hardly be called cough at all, but is rather a clicking or blowing sound.

On mirror examination, the interior of the larynx shows sometimes a catarrhal condition, sometimes anæmia, but more often no abnormality. The quickly repeated closure and opening of the rima can sometimes be observed with the laryngoscope, but more often it can not.

The diagnosis of the curious cough is not usually difficult if the examiner has assured himself that no organic lesion that might cause it has been overlooked. In addition, it must be remembered that a so-called "nervous" cough, very similar to the one under consideration, is sometimes present in the very incipient stage of phthisis.

6. The complicated inspiratory form is the severest and most dangerous. Its characteristic group of symptoms in children properly constitutes the picture which the designation "spasm of the glottis," or "laryngismus," calls up in the medical mind. This is well enough known; it is described as follows by Mackenzie (English edition, p. 483): "The first attack of laryngismus often comes on at night—frequently toward eleven or twelve o'clock, when the first sleep is passing off. It may occur to a child who up to that moment had seemed perfectly well, but more often the subject of the attack has been peevish and fretful for a few days before, has suffered from loss of appetite, and been restless at night, or a slight 'catch' has been noticed in its breathing. A severe fit of laryngismus may be thus described. A number of short, stridulous inspirations take place, each inspiration being a little longer than the preceding one, and the last being often very prolonged. Suddenly the sound ceases, the glottis is completely closed, and the respiratory movements of the chest are suspended. The flush which first suffused the countenance gives way to pallor and afterward to lividity. The eyes stare or the eyeballs roll, the head is thrown back, and the spine is often bent as in opisthotonus; the veins of the neck are turgid, the fingers close on the thumb, which is bent in the palm, and the hands are flexed on the wrist. Spasm likewise affects the feet; the great toe is drawn away from its fellows, the foot is flexed and rotated slightly outward. In some cases these so-called 'carpo-pedal' contractions are probably accompanied with great pain, and occasionally they are followed by general convulsions. Notwithstanding the severity of the paroxysm just described, it is not necessarily fatal; the patient may survive it, in which case the diaphragm soon relaxes, a stridulous inspiration is heard, air enters the lungs, and the spasmodic contraction of the feet and hands gradually yields. But, when the symptoms are of the dangerous character just described, the paroxysm is probably destined to be quickly followed by others, in one of which the child may die. In less severe cases all the symptoms are less marked, and the carpo-pedal contractions are often altogether absent. The attack frequently comes on while the child is at the breast. The infant suddenly stops sucking and looks round, its eyeballs are turned up, and after a second or two a loud crow is heard; the infant

then returns to the breast or the bottle, but only to be seized immediately afterward with a similar paroxysm. Sometimes each attempt to suck brings on such an alarming attack of spasm that the unhappy mother hesitates between the alternatives of starvation and suffocation. Again, in other cases, the attack assumes the form of a sudden, almost soundless, spasm, which does not relax till life is extinct. In very rare cases a slight but constant spasm is shown by stridulous breathing. In the common type of cases, when the attack has occurred for the first time at night, the child may appear to be quite well on the following day, and there may be no further return of the symptoms; but it more often happens that another attack comes on a few hours afterward, or at the same time on the following night. Sometimes the second attack supervenes almost as soon as the child has recovered from the first, in which event it is generally more serious, both in its character and duration, than the first. In severe cases, indeed, the paroxysms are so frequent that the child is scarcely out of one fit before it is again attacked. As a rule, there is an entire absence of pyrexia in these cases, though sweating of the head, so characteristic of the rachitic constitution, is almost always present. Now and then the patient may look healthy, and may even be plump, but, on closer examination, it will be found that the muscular system is weak, that the child is easily fatigued, and that it shows other signs of feeble organization."

PROGNOSIS.—The bases for prognosis are not generally understood. What Flesch says of infantile laryngismus is true of all cases of laryngeal spasm, viz.: "The progress is always doubtful, even in the simplest not complicated cases." I do not mean as to life, but as to recovery, for some spasms do not threaten life at all. The incarceration of the epiglottis between the larynx and pharynx, to which Cohen has first called prominent attention, is, of course, exceedingly dangerous. Last year, in speaking of Dr. Lefferts's two cases, in which there was complete or total spasm of the laryngeal adductor muscles, I used these words before you: "To this completeness is due the brief duration of each attack and thereby the safety of the patient. In incomplete spasm—that is, when not all the adductor muscles are affected—partial respiration but incomplete aëration of the blood may go on and lead to a fatal issue unless tracheotomy is performed; but the total spasm produces unconsciousness, whereupon the spasm relaxes and the attack is over." Prognosis as to life is largely influenced by this difference, but (and this is especially true of children) the unconsciousness of total spasm may pass into death. Mackenzie says: "The length of the intervals between the paroxysms is a good prognostic guide; the longer the interval the greater is the chance of recovery." And what Flesch says, in his article in Gerhard's "Hand-book of Children's Diseases," on infantile laryngismus, amounts to this, that he takes no responsibility for the first forty-eight hours, but then, with strictest following out of his orders, prognosticates certain recovery.

TREATMENT.—The treatment of laryngeal spasm requires often great promptitude, sometimes operative skill, and always good judgment.

Abductor spasm is so often found to be accompanied by (perhaps in some way dependent upon) paralysis of the adductor muscles that stimulation of these is an integral part of its therapeutics. Indeed, even in the case in which the adductors were proved to be intact, their stimulation by strychnine and galvanism was the only treatment resorted to, and was successful in curing the patient.

In adductor spasm attention must be paid to the paroxysm, to the intervals between the attacks, and to prophylaxis. In infantile laryngismus, regulation of the child's diet is of the utmost importance. Fleisch, who has had great success in treating this disease, relies mainly upon it. He commences the treatment with an enema, which, if not effectual, is repeated after some hours. If the child suckles, he prohibits every other food, allows nursing every three hours only, and orders rest, fresh air, and other hygienic care; if the child is hand-fed, milk, at first diluted with an equal quantity of water (and gradually less diluted), is given at intervals of three hours, and only once a day meat-broth, the fæces being examined daily. Cod-liver oil and iron are given to rachitic children, and farinaceous food is absolutely forbidden.

When, as is usually the case, especially in children, the paroxysm lasts but a very short time, it is best to do nothing but keep the patient from harm. Altogether, the various antispasmodic measures and remedies that can be tried are too well known to necessitate my recounting them on this occasion.

There is only this that I want to say to you in conclusion, and I want to say it with great emphasis, viz.: *Ward off asphyxia in all prolonged and life-endangering adductor spasms; thrust the forefinger deep into the throat to discover whether the epiglottis is impacted, and, if so, release it, draw the tongue forward, etc.; if necessary, catheterize the trachea, particularly by means of Schrötter's three-cornered hard-rubber tubes, and add to this artificial respiration until spontaneous breathing is again carried on; and perform tracheotomy in all appropriate cases without hesitation.*

DISCUSSION.

Dr. INGALS inquired what sized catheters the author would consider necessary for children of various ages.

Dr. JARVIS asked Dr. Elsborg if he did not consider laryngeal growths one of the causes of spasm of the glottis. By that, said he, I mean to say that previous to the appearance of the growth no such condition may exist, but after removal of the growth spasm of the larynx continues, although no vestige of the tumor remains. In the case narrated by me yesterday no trace of the tumor remained after the operation, yet tickling of the larynx with the point of the probe caused very marked spasm. Under ordinary circumstances such spasm did not occur.

Dr. ROE said: I have seen a number of cases of spasm, and have never failed to relieve them by the use of chloroform. Last year I saw a case of spasm of the larynx due to irritation of the arytenoids. The patient was reduced almost to a state of starvation. By removal of the irritable condition, she gradually acquired courage to swallow, but it was only by the moral support of my presence, as I assured her that the means were at hand for her ready relief in case the spasm should again occur.

Dr. ELSBORG, in closing, said: I alluded in my paper to hyperæsthesia, such as Dr. Jarvis spoke of, as one of the causes of

spasmodic contraction of the muscles of the larynx. The case of Dr. Roe's is typical of one which I have in mind of deglutitory adductor spasm. I also regard chloroform as one of the best means for relieving the spasm, although it really, and especially in children, is a very dangerous remedy, and should be used in adductor spasm with very great circumspection. As to the point raised by Dr. Ingals, with regard to the size of the catheters to be used in children of different ages, I preferably use hard rubber catheters, especially those of Schrötter, but, of course, in a hurry any catheter may be employed which can be got through the rima glottidis. I employ tracheotomy-tubes of six different sizes. They are marked by the instrument-makers in the metric system, but, for convenience of memorizing, they are also marked in inches, as follows: One sixth, one fifth, one fourth, one third, five twelfths, and one half of an inch. My rule as to the age for which these sizes should be used is that during the first year I advise one sixth; from one year to three, *i. e.*, one multiplied by two, plus one, the next size; for from three years to twice three, plus one, *i. e.*, seven years, the third size; for patients from seven to fifteen (*i. e.*, twice seven, plus one) years old the fourth size; for boys over fifteen, and women, the fifth size; and so on, the largest size being employed in men or with specially large throats only. The appropriate catheter corresponds to these sizes and ages, only I select them, if possible, a trifle smaller.

EXTRA-UTERINE PREGNANCY,

WITH AN ACCOUNT OF TWO CASES AND THEIR TREATMENT.*

By NATHAN BOZEMAN, M. D., NEW YORK,

SURGEON OF THE WOMAN'S HOSPITAL OF THE STATE OF NEW YORK.

I THINK I am safe in saying that it has only been by the closest and most careful study of the diagnosis of some of the graver diseases of women that surgeons have been enabled to surmount the difficulties of treatment, and to give to the department of gynecology those brilliant practical results in which our own country claims so large a share. This fact finds illustration in the advances made in the study of uterine and ovarian tumors, of the various injuries incident to parturition and their complications, and, more recently, of the necessities of prompt laparotomy in connection with tubal pregnancy. The manner in which this high aim of scientific thought has been carried out, and the results thereof utilized in the several lines of investigation indicated, it is not my purpose on the present occasion to discuss.

I propose simply to speak of the dangers of extra-uterine pregnancy, its treatment, and the importance of early and accurate diagnosis in this condition, as illustrated by two interesting cases of this abnormality which have recently come under my observation.

The dangers of extra-uterine pregnancy as dependent on anatomical conditions resolve themselves, practically, into, *first*, the immediate, and, *second*, the remote. The immediate dangers are those arising, within the earlier months of pregnancy, from the lodgment and growth of the impregnated ovum in some portion of one or other of the Fallopian tubes, the dangers of the lodgment always decreasing in the ratio of its approximation to the abdominal extremity. The remote dangers are those pertaining to the impregnated

* Read before the New York State Medical Association, November 19, 1884.

ovum as regards its growth and development, possibly to full term, in its relationship with the ovary alone, with the ovary and fimbriated extremity of the Fallopian tube jointly, or with some point in the peritoneal cavity, whether before or after the death of the fetus, or whether in connection with normal pregnancy as a complication.

With regard to the study of the diagnosis of tubal pregnancy, and the immediate dangers arising from rupture of the cyst and the resulting hæmorrhage, I feel warranted in stating that a more important and practical impulse was given the subject in 1867 than at any time previous by the late Dr. Stephen Rogers, of this city ("Transactions of the American Medical Association"); and, for the deductions then made as to the proper kind of treatment, science is certainly under lasting obligations to him.

It is true that Dr. Rogers contributed no astounding record of successful clinical results from his careful study and observations in connection with the subject, but what he did leave as a precious heritage to us was his earnest conviction that the immediate dangers above indicated should always be met and combated by a prompt resort to the operation of laparotomy and the controlling of hæmorrhage wherever found in the abdominal cavity—a principle of practice which has only been fully recognized and appreciated within the last year or two.

I confess it was the close study of the diagnosis as found embodied in his able memoir that first imbued my mind with the importance of the subject, and determined me to make an application of the teachings therein inculcated whenever an occasion offered.

Notwithstanding the great strides that have been made in gynæcology since the date of Dr. Rogers's publication, comparatively little has as yet been accomplished toward placing the important principle of practice enunciated by him upon a sound basis, and disarming tubal pregnancy of the terrors that have so long surrounded it.

To Mr. Lawson Tait, of England, more than any surgeon in any country, we are indebted for successful clinical results which not only stamp the procedure with a value never dreamed of by Dr. Rogers, but at once place it in the foremost rank as regards practical availability and usefulness. In an article entitled "Five Cases of Extra-uterine Pregnancy operated upon at the Time of Rupture" (*"British Medical Journal,"* June 28, 1884) he says: "I desire to place on record this, the first series, as I believe, of cases of extra-uterine pregnancy operated upon at the time of rupture—that is, from the tenth to the thirteenth week." After speaking of the difficulty of diagnosis, and the doubts arising therefrom as to the propriety of operative interference in this class of cases, he further says: "If, however, it be found that the patient has been eight weeks or more without a period, that there is a pelvic mass fixing the uterus and on one side of it, and that sudden and severe symptoms of pelvic trouble come on, the rupture of a tubal pregnancy may be at once suspected, and if an operation is to be done, and it clearly ought to be done, it must be done without delay."

In conclusion, in speaking of the pathology, and of the results obtained by him, he says: "These cases all confirm

the view of the pathology of extra-uterine pregnancy which I advanced many years ago, that in origin it is always tubal, and that its varieties depend merely on the direction in which rupture occurs. These results also confirm the soundness of the policy of interfering early in such cases, for four cases out of the five have been easily and completely cured of one of the most formidable conditions of pregnancy."

Nearly a year ago Dr. Charles K. Briddon, of this city, recorded (*"Annals of Anatomy and Surgery"* for Dec., 1883) a most interesting case of tubal pregnancy in which rupture of the cyst occurred in the eighth week, and he was called upon to operate (Oct. 29, 1883), under circumstances truly appalling, on account of the suddenness and profuseness of the hæmorrhage. He says: "Part of the ovum, one inch and a quarter in diameter, was found protruding from a rent in the left Fallopian tube close to its uterine extremity." The patient, a young and healthy woman, perished at the end of forty-seven hours. So far as I know, this was the first operation of the kind performed in this country.

Strange to say, it was only two or three weeks after reading Mr. Tait's article that I was called upon (August 21, 1884) to operate in my first case of tubal pregnancy, after an experience in the profession of over a third of a century. This case and another one of abdominal pregnancy, to which I was called in consultation only a month later, form the basis of this communication.

I will not here point out particularly the line of practice by which the remote dangers of abdominal pregnancy are to be met. Dr. T. G. Thomas and other writers have already brought this part of the subject prominently before the profession, and have shown excellent clinical results.

Next as to the prevention of the immediate dangers of extra-uterine pregnancy by the employment of electricity. This principle was first applied by Bachetti, of Italy, 1852, Braxton Hicks, of England, 1866, and in our own country by Joshua B. Allen, of Philadelphia, 1869. See article entitled "Electricity in Extra-uterine Pregnancy," by Henry J. Garrigues, A. M., M. D. (*"Trans. of the Am. Gynæcolog. Society,"* 1882, p. 184). The practice has for its object the early destruction of the life of the growing fetus, and, consequently, the prevention of rupture of the tube-cyst. The proposal of such a method of treatment, and the almost universal satisfaction that has attended its employment up to the present moment, must be regarded as the strongest evidence that could possibly be offered of the close study of the subject and of the great value of the principle.

It is to be clearly seen, from the acknowledged success attending the employment of the principle, especially in tubal pregnancy, that, in skillful hands, it will at no distant day supersede entirely the plan of quietly trusting to luck, by means of which so many valuable lives have been sacrificed.

But the difficulties surrounding this practice, notwithstanding its wider range of application, can not be compared with those attending the operation of laparotomy. Each principle, however, has its sphere of usefulness, and the reasonable application of electricity, as indicated by the con-

clusions of careful diagnosis, can not fail in the future to yield the most encouraging clinical results.

It should unquestionably be the rule, in all cases of extra-uterine gestation seen in the earlier months, to destroy the life of the fœtus, and, even in cases where this condition is suspected but the diagnosis is open to doubt, to apply electricity, which, for safety and certainty, is emphatically *the remedy*. With this principle more widely recognized, there will be fewer instances demanding a resort to the graver procedure of laparotomy, and it is to be hoped that the matter of diagnosis and the employment of this mode of treatment may eventually become so accurate and effective that there will be no occasion for the latter operation.

A word now with regard to the ætiology and mechanical philosophy of extra-uterine pregnancy—points which I need scarcely say are difficult of explanation. The belief has become generally accepted that women with long-enforced sterility after fruitfulness are more prone to ectopic gestation than those passing through the fruitful period of their lives in the regular exercise of their procreative functions; but exactly why a certain number of widows should be more liable to it than an equal number of married women no satisfactory reason has as yet been assigned, and probably never will be. I think, myself, the explanation is to be found in the backward displacements of the uterus.

I maintain that in retroversion, and especially in retro-lateroversions of the organ, one ovary is often dragged down and fixed, with a corresponding displacement of the Fallopian tube, at a lower plane in the pelvis than that of the same structures on the opposite side, and that, as a result of such malposition, there is necessarily more or less rolling or turning of the uterus to the affected side. By this form of displacement not only is the axis of the uterus placed on a horizontal line with that of the vagina, but the entrance into the uterus of the Fallopian tube on the same side is depressed to a lower level than the opposite one—a change of relationships in all these parts and in their aptitudes, as regards the cervical canal, the plane of the cavity of the uterus, and the utero-tubal orifice, highly favorable to the entrance of the spermatozoa and their migration on one continuous line. In the reversed order of relationships of the same structures, and from the same anatomical considerations, the aptitude of the affected Fallopian tube in its lower or fimbriated extremity to receive and to convey the ova from the corresponding ovary is in a like degree diminished. From the movements, then, of the spermatozoa out of the vagina, almost unopposed by physical obstructions and the operation of gravity, and of the ova coming from the corresponding prolapsed and fixed ovary almost completely opposed by the law of gravity, it is easy to see that the chances, mechanically considered, are altogether in favor of the former reaching the depressed utero-tubal orifice instead of the elevated one, and falling into the Fallopian tube itself, as into a deep well, to meet, at some point in their descent (perhaps in the fimbriated extremity of the tube or upon the surface of the corresponding ovary), an ascending or stationary ovum or ova ready in some one of these localities for the impress of fructification or conception and gestation.

To these pathologico-physiological conditions of the uterus and its annexa, with the physical phenomena of abnormality regarding the performance of their functions pointed out, may we not therefore reasonably ascribe the occurrence of ectopic gestation, rather than to the length of time of widowhood after fruitfulness, the latter itself presupposing the sequelæ of retro-lateroversion, the first link in the chain of morbid results?

What the force is inherent in the two essential elements to conception to insure their movements independently of natural laws, and to impart the spark of life when their contact is effected in situations other than in the uterine cavity, I do not pretend to know. This remains for the physiologist to explain.

But, as proof of the possibility of the spermatozoa in their migrations in the vagina and uterus, surmounting seemingly the gravest obstacles in reaching their usual destination in the latter organ, it is only necessary to refer to the well-attested instances on record of impregnation taking place without rupture of the hymen, among which are the notable examples recently cited by Professor Karl Braun. I have myself seen extraordinary instances of their power to accomplish their work of impregnation in the face of the greatest obstacles. In one case in my practice which I now recall there was a continuous flow of urine from the os uteri all the while, arising from a vesico-utero-cervical fistule high up. Here they stemmed the opposing current of urine, so to speak, and reached their destination in the cavity of the uterus, with the result of conception, gestation, and safe delivery of child. In another case which I saw with Sir Spencer Wells in Heidelberg, in the autumn of 1874, in the practice of the late Professor Gustav Simon, a vesico-vaginal fistula, complicated with stenosis of the vagina, had been operated upon by this eminent surgeon for incontinence of urine, a year or two previously, by shutting up the mouth of the vagina (kolpopleisis) about half an inch behind the meatus urinarius. The operation was successful, with the exception that an orifice of the size of a cambric needle was left, and, strange as it may seem, the spermatozoa entered through this minute fistulous tract, traversed the vagina, though stenosed and acting as the receptacle of the urine from the bladder, and finally made their entrance through the os uteri into the cavity of the organ. The result was conception and gestation; but a sad termination, as might well be imagined, attended the labor. In both of these cases there was marked retroversion of the uterus.

This digression may be thought irrelevant, but the facts presented are interesting, I think, in connection with my subject, as showing some of the possibilities of normal pregnancy under circumstances seemingly but little less difficult of explanation than those overhanging the causation of extra-uterine gestation.

I shall now present the histories in detail of my two cases of extra-uterine pregnancy, their treatment and results.

CASE I.—*Right Tubal Pregnancy, end of the Twelfth Week; Rupture of Cyst; Profuse Hemorrhage; Laparotomy on the Thirteenth Day; Death.*—This case I first saw, August 16, 1884, in consultation with Dr. R. Burns, of Honesdale, Pa., from

whose very full report I am permitted to present the following points regarding the history and treatment:

Mrs. G., of Honesdale, aged thirty, says that she first menstruated at the age of thirteen, married at nineteen, miscarried at twenty-four, and was delivered of a full-term child at twenty-seven. The labor was difficult, and instruments had to be used, but her health was afterward good. She married the second time, at twenty-nine, in October, 1883.

On May 9, 1884, menstruation, which had been regular and normal during all her married life, except when pregnant, appeared for the last time, and continued four or five days as usual. On June 6th it appeared for one day only, and on July 4th it failed entirely. She now had slight nausea, and after a week or two she began to have colicky pains in the right iliac region, with a slight sanguinolent discharge. On July 23d, her pains being more extended over the lower part of the abdomen than usual, she discharged from the vagina a membranous substance about one third the size of the hand. A digital examination by Dr. Burns showed the uterus to be enlarged and tender, with a patulous os, and, by conjoined manipulation, considerable pain was caused in the right iliac region. On August 3d the patient walked to church and back, about a mile altogether, and afterward suffered from severe pain in the back and right side. A hypodermic injection of morphine was required to afford relief. After this colicky pains, attended by more or less nausea and vomiting, recurred every few days until Saturday night, August 9th, when they became so violent as to require several successive hypodermic injections of morphine before they could be relieved. Next morning the patient was much prostrated. She looked pale, and suffered from nausea and vomiting, with feeble pulse and vesical tenesmus. A digital examination then made showed the uterus to be crowded forward and upward behind the pubes, and Douglas's pouch to be filled with a soft, doughy mass protruding into the vagina, extending upward into the right iliac region, and pressing the uterus to the left side. The uterus was enlarged, being about four inches long, while its fundus could be easily felt two or three inches above the brim of the pelvis. When pressure was applied, great pain was complained of across the entire lower part of the abdomen and in the vagina. There was a bloody discharge from the latter all the while. The diagnosis naturally made was that of pelvic hæmatocele arising from bleeding vessels probably situated in the right broad ligament.

The patient was kept quiet with opiate enemas, and given liquid food when the stomach would tolerate it. Progress was satisfactory for a couple of days, there being no apparent increase of the size of the pelvic mass. On the third day, August 12th, the patient was seized with the same violent pains as at first, for which a hypodermic injection of morphine, and afterward chloroform by inhalation, were used before relief was obtained. After this attack there was a perceptible increase in the size of the supposed hæmatocele, as well as an augmentation of the prostration, nausea, and vomiting, with more feeble pulse, though there was little or no elevation of temperature. Retention of urine now occurred, requiring the use of the catheter. On August 14th there was a similar attack, with an aggravation of all the symptoms, and the same treatment was repeated.

On August 16th, two days later, in response to a telegram, I first met Dr. Burns in consultation in the case. From my examination I found the ordinary signs of pregnancy present, including the cessation of regular menstruation for nearly twelve weeks, deepened aureole, and increased prominence of the surrounding papillæ. These, associated with the foregoing history, all pointed, as I conceived, to tubal pregnancy and to rupture of the tube-cyst, the hæmorrhage having caused the doughy

mass in Douglas's pouch. I stated my views to Dr. Burns, and said that, had I seen the patient soon after the rupture of the cyst occurred, I should have recommended immediate laparotomy in order to clear the pelvic and abdominal cavities of blood, and secure the bleeding vessels, as sanctioned by the highest authorities; but that, as seven days had then elapsed, and the favorable condition of the patient, as shown by an improving pulse of 90, without elevation of temperature, warranted the hope of an ultimate recovery without an operation, I should advise waiting for further developments. The doctor coincided with me fully in the latter view, and with this understanding I returned home.

On Tuesday evening, August 19th, Dr. Burns apprised me by telegraph of the failing condition of the patient, and requested me to come prepared to operate. When I arrived at Honesdale the next afternoon I found the symptoms very markedly changed for the worse. The most pronounced of these were persistent and agonizing nausea and vomiting, with a small, feeble pulse of 110, which indicated further loss of blood, and this unfavorable change had been going on for about forty-eight hours. On examination, I discovered that, while there had been no perceptible increase of the mass of blood behind the uterus during my absence, the evidences of its extension in the right iliac and hypogastric regions were manifest. Here I was able to note with precision the increased size, and to map out through the abdominal walls a valuable diagnostic feature which I could not then explain. This was an apparently round body of about one third the size of the fist. It stood on a level with the fundus of the uterus, and was quite immovable. Around it I could detect a peculiar condition somewhat similar to that of emphysematous pulmonary tissue when compressed between the fingers.

The only thing now to be done, I conceived, was to open the abdomen and secure the bleeding vessels, and, accordingly, at three o'clock in the afternoon of August 21, 1884, the patient being under the influence of ether, the operation was begun with all the usual antiseptic precautions. There were present Dr. Burns, Dr. Reed, Dr. Niles, and Dr. O'Connell, of Honesdale, and my assistant, Dr. R. B. Talbot, of New York. On making the usual incision between the umbilicus and pubes, and opening the abdomen, there was a gush of a pint or more of bloody serum. After this was over, and the peritoneal cavity exposed, clots of blood were to be seen among the intestines in every direction. There were no plastic exudations or other evidence of peritonitis. On examination, I now found the hard, rounded, immovable body, previously felt through the abdominal wall, to be the right Fallopian tube, greatly distended and looking like a large sausage doubled upon itself. The corresponding ovary, which could not then be felt, was fixed deep in the pelvis, and to it the upper part of the funibriated extremity of the tube seemed to be adherent, thus accounting for its peculiar form. So tense and resisting was this distended portion of the tube that no movement of it in any direction could be made during my search for bleeding vessels. Next I passed my hand into Douglas's pouch, expecting to find there the large blood-clot as diagnosed from the vagina, but in this I was mistaken, the clot here being felt in front through an intervening membrane. I then again turned my attention to the distended Fallopian tube, this time passing my index-finger below and under the concave side of it through what seemed to be an open space. Here, at a point near the middle of the tube, the finger entered a rent through which there was a direct communication of its contents with the peritoneal cavity and with the *cul-de-sac* below containing the blood-clot, but no fetus was discovered.

From this point I now directed all of my fingers and then

my whole hand into the *cul-de-sac*, where I found the blood-clot for which I had vainly searched in Douglas's pouch. I scooped out handful after handful of dark clotted blood—twenty ounces or more—until finally I reached the bottom of this abnormal *sac*. The boundaries of this were the detached peritonæum behind, and the uterus with the upper part of the posterior wall of the vagina in front, the usual situation of a pelvic hæmatocele.

Having thus finished this step of the procedure, I, for the third time, directed my attention to the enlarged Fallopian tube with the intention of removing it, and in that way controlling the hæmorrhage which was the result of the rent in it. The tube was now found to be quite movable, and without difficulty I succeeded in applying a ligature around the broad ligament between the distended portion of the tube and the uterus, and half an inch from the latter. This being done, the structures were divided on the distal side of the ligature. Another ligature was then thrown around the structures outside the distended portion of the tube as near as possible to its fimbriated extremity. Here the division of the parts was made on the proximal side of the ligature, including the ruptured portion of the tube. This completed the excision of the injured and distended portion of the tube, and afforded complete control of all the bleeding vessels.

The abdominal cavity and the emptied *cul-de-sac* described were thoroughly cleansed, and a drainage-tube placed in the latter. The abdominal incision was closed in the usual way, and antiseptic dressings were used. The operation lasted one hour, and the patient received during the time one ounce of brandy hypodermically. She came out from the influence of the ether fairly well, considering the circumstances, and her general condition was thought to be hopeful for several hours; but her pulse and temperature soon began to go up, the former beating from 140 to 150. In addition to this, her almost incessant nausea and vomiting, from which she had suffered so terribly before the operation, returned; so that we had scarcely any hope of a favorable issue almost from the beginning of the after-treatment. Nevertheless, nutritive and stimulating enemata, with quinine and opium, were perseveringly used, and everything possible was done to quiet the stomach; but it was all to no purpose. Her condition gradually grew worse, and she died thirty-three hours after the operation.

I have here in this jar the distended portion of the Fallopian tube, showing the original bed of the fœtus, and am indebted to Dr. H. C. Coe, Pathologist of the Woman's Hospital, for the examination and report upon the specimen. He describes it as follows:

"Length of specimen 9 ctm., of which 6 ctm. belong to the tube, 3 ctm. to the portion of the blood-clot, which projects beyond the torn end of the tube. Weight, 80 grammes.

"The specimen has a regular sausage shape, both ends being smoothly rounded off. Two portions may be distinguished—one a blood-clot, being firm, non-elastic, and without any semblance of fibrous structure, the other being evidently membranous in character.

"The dilated tube contracts toward its proximal end, where there is a small portion of the original canal (about $1\frac{1}{2}$ ctm. long) which admits a fine probe for a short distance. On making a section through the entire mass (along what was doubtless its upper surface), the following appearances are presented:

1. "The tube itself expands suddenly $1\frac{1}{2}$ ctm. beyond its proximal end, the walls being greatly thinned, and the original character of its lining lost. It is filled with a blood-clot, which is continuous with the mass which protrudes from its torn distal end. The clot has contracted so that it is not everywhere in close contact with the sides of the tube.

2. "At the proximal end of the tube there is a sort of partition, apparently formed by a fold in the tube. This would have acted as a barrier to the passage of blood inward toward the uterus; hence the clot is abruptly rounded off at this spot."

I have said in the description of the operation that no fœtus was discovered. This is liable very often to happen on account of the escape of the body into the peritoneal cavity, or of its becoming disintegrated and lost in the mass of clotted blood, which in this case amounted to over a pint. Mr. Tait had the same experience in nearly all of his cases. The clot found in the distended tube, constituting a true *hæmatosalpinx*, resulted from the bleeding vessels of the ruptured point in the cyst after the escape of the fœtus. The partition formed by the fold near the uterine end of the tube was the result, no doubt, of nature's provision for the bed and protection of the impregnated ovum. The loop of silver wire on the under side of the specimen indicates the proximal angle of the rupture of the cyst.

CASE II.—*Abdominal Pregnancy; Death of the Fœtus about the Sixth Month; Normal Pregnancy about Three Years and Two Months afterward; Death of the Child in the Eighth Month; Delivery with Forceps; Remains of the Fœtus in the Abdomen removed through an Opening in the Posterior Wall of the Vagina at the Same Time; Recovery of the Patient.*—I was requested by Dr. John Burke, of this city, to see this case in consultation, September 18, 1884, and he permits me to report it as follows:

Mrs. K., aged thirty-eight, who had been delivered of six living children without difficulty or injury to herself, became the subject of abdominal pregnancy after a regular menstrual period, which terminated January 24, 1881. She stated that the flow had always appeared three or four days in advance of the time, but that the duration was natural. On March 14th, seven weeks from the cessation of her last period, she was awakened out of a sound sleep about midnight by a violent pain across the lower part of the abdomen, soon followed by severe nausea and vomiting. She did not remember on which side the pain was greatest. A physician in the neighborhood was called in, who administered a hypodermic injection of morphine, which gave prompt relief. For two or three days there was tenderness of the abdomen, attended by a slight bloody discharge from the vagina. After this the same physician made a vaginal examination, and discovered, as he thought, retroversion of the uterus, for which he introduced a pessary. The instrument, however, was worn only a few days, so much pain and discomfort being caused by it that it had to be removed. This was done March 28th by Dr. Burke, the family physician, who was now called in for the first time, and who was obliged to give a hypodermic injection of morphine for the relief of pain. This was about nine weeks after the date of the last menstruation, in January. The bloody vaginal discharge still continued, and an examination now revealed the existence of a large and rather elastic mass, which was painful under pressure, situated to the right of the uterus. There was also slight enlargement of the latter, and the organ was pressed to the left side. After a few days the abdominal pains in the right iliac region disappeared, together with the bloody discharge from the vagina. The patient had no knowledge of a discharge of anything like a decidua membrane, nor did she refer to symptoms indicating the probability of pregnancy. Dr. Burke's diagnosis was pelvic hæmatocele.

In the latter part of June, 1881, the patient went to the seaside, where she rapidly improved in health and strength. In August, about seven months after her last menstrual period, she

noticed a slight show, which she regarded as a re-establishment of the function. Her size at the time, she thought, was that of a woman at the fifth or sixth month of pregnancy.

In September she returned to the city. Dr. Burke now made an examination, and discovered low down in the abdomen a tumor, having (as felt through the vaginal wall) all the characteristics of a fetal head. Its size was that of the head of a child of five or six months' growth, and it presented behind the uterus. The case was seen in consultation a few days later by an eminent gynecologist of this city, who declared the existence of abdominal pregnancy.

Soon after this, October 6th, menstruation came on naturally, and the patient felt perfectly well, with the exception of an occasional attack of neuralgia in the right side of the face. Indeed, so well was she at this time that she did not wish any further notice taken of her case, though the enlargement of the lower part of the abdomen still continued.

In the autumn and early winter of 1883, nearly three years after this pregnancy, her general health in the intervals between her neuralgic attacks, which had continued up to this time, was better than ever before. The enlargement of the abdomen seemed to her by this time to be greatly reduced, and much lower in situation.

In the last week of January, 1884, her menstruation appeared as usual, lasting four days; but it did not return in February, March, or April. At this time the facial neuralgia became more frequent and severe, and soon the pain extended to the teeth, and thence to the whole side of the body as far down as the toes. A dentist was consulted, who extracted several teeth, including some sound ones, but with the result of causing but little abatement of the suffering. Owing to the unpleasant effects of morphine upon the patient, Dr. Burke put her on the use of Duquesnel's aconitine, the ninetieth of a grain three times a day, which was followed very soon by marked diminution in the severity of the pain.

In this way matters went on a few months longer, when the patient's attention was directed for the first time to an increase in her abdominal enlargement; but, feeling a repugnance to having an examination made as to the cause of the change, she decided not to ask medical advice.

It was not until September, over seven months after the last appearance of the catamenia, that Dr. Burke was consulted. He, of course, insisted upon an examination, and the result was that he found in the abdomen a somewhat solid and rolling body, with an unusually marked degree of prominence anteriorly. Having three years before closely watched the case for months as one of abdominal pregnancy, he naturally concluded that the present enlargement of the abdomen might be attributed in some way to the products of that conception.

On September 18, 1884, several days after his examination, he requested me to see the case in consultation. The former abdominal pregnancy being now overshadowed by the actual existence of a new growth, my attention was directed especially to this.

From the general good health of the patient, and the presence of most of the rational and physical signs of pregnancy, as well as from the evidence afforded by palpation, I was at once led to eliminate the existence of uterine and ovarian disease, and to decide that the enlargement was probably due to the presence of a fetus *in utero*. I even thought I heard the pulsations of the fetal heart, but in this I was mistaken, as the result proved. Further examination, *per vaginam*, however, disclosed the fact that the patient was actually in labor.

Two peculiarities of the presentation of the child attracted my attention: 1. The prominence of the head felt through the expanded anterior segment of the cervix uteri; and, 2. The

difficulty of reaching the os uteri with the finger. Only the anterior margin of this could be touched, and this condition of affairs I attributed to the forward inclination of the body of the uterus, in consequence of the presence of the remains of the abdominal fetus.

After this Dr. Burke, with his friend, Dr. McSweeney, conducted the labor, and delivered the child, with forceps, after eight or ten hours. The child proved to be of about seven and a half months' growth, and had evidently been dead for several days. Immediately after the completion of labor an uneven and projecting mass presented in Douglas's pouch, which was recognized through the vaginal wall as the remains of a fetus encysted in this locality. Dr. McSweeney, with the sanction and approval of Dr. Burke, made a longitudinal incision just below the cervix uteri into the cyst, and with a pair of forceps removed the several portions of it. The patient recovered without an untoward symptom, and when I saw her with Dr. Burke, some three weeks ago, she was the picture of health, having even lost her facial neuralgia. An examination showed the uterus to be but slightly enlarged and anteverted. Only the line of cicatrization in the posterior *cul-de-sac* remained to indicate where the incision had been made for the removal of the abdominal fetus.

Dr. Burke's reasons for removing the encysted fetus, as was done, was that it had presented at the most favorable point possible for an operation, and that he feared the future health, and probably the life, of the patient might be jeopardized by a longer continuance of its remains in the abdomen.

I present here the products of the abdominal pregnancy, preserved by Dr. Burke, and I have also in alcohol the intra-uterine product, a well-formed child of seven and a half or eight months' growth, which possesses no other interest than the fact of its conception, development, and delivery during the time of the presence of the former fetus in the abdomen.

The first specimen, consisting of wet and dry preparations, is interesting in at least three particulars: *First*, in having sojourned in the abdomen encysted from July, 1881 (when death took place at six months), to September 18, 1884—about three years and two months—and in having been removed, through an incision made into the cyst through the posterior wall of the vagina, a few minutes after the extraction of the normal fetus with forceps; *second*, from the fact of the soft parts having been almost entirely removed by absorption, there remaining scarcely anything save the bones, tendons, dura mater, and some portions of the skin; and, *third*, in having caused the mother, prior to and during her subsequent pregnancy, so little trouble or inconvenience, the general health remaining good the whole time indicated, with the exception of the paroxysms of neuralgia mentioned. The fingers and toes and the features of the face are easily distinguishable in the wet preparation.

The points brought out in the preceding pages justify, I think, the following conclusions:

1. That retroversion and retro-lateroversions of the uterus, and the consequent changes in the relationship of its appendages, contribute largely toward explaining the causation of extra-uterine pregnancy.

2. That extra-uterine pregnancy probably has its seat originally in one or other of the Fallopian tubes, and that the abdominal varieties of it occur afterward from rupture of the tube (Tait), or by partial or complete escape of the

impregnated ovum from the fimbriated extremity of the same.

3. That, after completing the diagnosis of tubal pregnancy between the seventh and fourteenth weeks, it is of urgent importance in all cases to destroy the life of the fœtus, without delay, by electricity, the surest and safest method at our command, in order to guard the individual against the immediate dangers of rupture of the cyst, now liable to take place at any moment.

4. That the practitioner, if he does not himself feel competent to meet the threatened danger of rupture of the cyst by prompt surgical interference, should at once summon to his aid a surgeon prepared to carry out his wishes at a moment's notice.

5. That the surgeon, where rupture of the cyst occurs, as indicated by the usual symptoms of shock and loss of blood, should open the abdomen and secure the bleeding vessels without delay, success in all cases depending on the promptness and thoroughness of the procedure.

6. That the differentiation of the particular variety of ectopic gestation existing is of no consequence at this early stage, the treatment before and after the rupture of the cyst being the same in all cases.

7. That, when abdominal pregnancy is diagnosed at a later period of gestation, whether seated partially in the fimbriated extremity of a Fallopian tube or entirely within the peritoneal cavity, electricity should still be promptly employed, on the assumption that the earlier the life of the fœtus is destroyed, the less grave will be the remote dangers arising from disintegration, absorption, suppuration, ulceration, and the use of the knife.

8. That, in all cases of abdominal pregnancy, the fœtus becomes encysted more or less completely, and that, whether its life be destroyed artificially, or it dies before or at the full term of gestation, it is liable to complicate a subsequent normal pregnancy by obscuring its diagnosis and seriously interfering with natural labor.

9. That, when normal labor occurs with pre-existing abdominal pregnancy, it should be allowed to progress to its natural termination, the practitioner, of course, assisting the delivery with instruments when demanded; but that, in the event of the dead fœtus presenting in Douglas's pouch as an impediment to the normal labor, or as a prominent projection from the same locality into the vagina, immediately after the completion of labor the cyst should be opened and emptied of its contents, the delivery of both fœtuses thus being completed at the same sitting.

I will now briefly refer to a third case of extra-uterine pregnancy which I saw in consultation with Dr. J. F. Chauveau, of this city, November 10, 1884, for the purpose simply of showing how the treatment with electricity was carried out, it being too soon after the occurrence to report it in full. It happened in a young woman, aged twenty-five, in the twelfth week of her second pregnancy, and was found to be of the tubal variety, on the left side, the uterus being retroflexed. The diagnosis was clearly made out, in the recumbent and knee-face positions, even to the extent of proving with the finger the vacuity of the uterus. The result of the consultation was the resolution to destroy the life of the

fœtus with as little delay as possible. Dr. A. D. Rockwell was called in to apply the electricity, November 13th, the form preferred by him being the interrupted galvanic current. The negative electrode was applied *per vaginam* to the pelvic mass to the left of the uterus, and the positive over the enlargement in the left iliac region, at its most painful point, the current being thus established through the structures. A series of twelve cells, gradually increased to fifteen, was employed, and the interruptions were about one hundred per minute. The *séance* lasted five minutes, with momentary intervals of rest. The patient bore the treatment well, complaining of little or no pain. Four applications were made from November 13th to 17th, the first three on successive days, and the fourth after an interval of one day.

Dr. Rockwell's opinion was that one application, as above described, was sufficient to destroy the life of the fœtus; but, as there was no way of determining this fact positively, he thought, in order to be sure, the patient should be subjected to at least four *séances*.

Note, December 9, 1884.—With this the treatment was concluded, and the patient believed to be protected against the dangers of rupture of the cyst; but, about sixty hours after the last *séance*, she was seized with another violent paroxysm of pain in the same region as before, which soon extended to the whole lower part of the abdomen, and even to the corresponding thigh. I now saw the patient in consultation with Dr. Chauveau the second time, and, from the great tenderness still felt in the parts, we concluded that the treatment had not been effective in the object of its use. Dr. Rockwell was accordingly requested to see the case again, which he did November 20th, and he then made a fifth application of galvanism, with the same number of cells and in the same way as before described. The result so far has been entirely satisfactory.

I saw the patient with the family physician this afternoon, and made an examination. She had just passed her menstrual period, menstruation having before been absent for nearly four months. It is now twenty days since the last severe paroxysm of pain, and she feels quite well, except for weakness resulting from confinement to bed. The uterus is almost natural in size and quite movable, but it is still retroflexed, with a well-defined enlargement above and to the left side of it. The enlargement seems to be of about the size of a Sicily orange. It is considerably more movable, and very much less painful under conjoined manipulation, than it was at my last examination. From these circumstances and characteristics, therefore, I think it may be clearly inferred that the life of the fœtus was destroyed at the fifth *séance* with the galvanic current, and that no further trouble from its growth need be apprehended.

The Diagnosis of Pelvic Inflammation by the Temperature of the Urine.—Betz ("Memorabilien") states that the temperature of the bladder, and hence that of the urine contained in it, is affected by that of the surrounding tissues. Therefore, in inflammatory conditions of the pelvic cellular tissue and peritonæum, the patient often complains that her urine feels "hot." If cystitis can be excluded, it is quite probable that this symptom points to some inflammation in the neighborhood of the bladder.

THE CURETTE;

ITS PLACE AND ITS POWER IN
UTERINE THERAPEUTICS.*

By GEORGE T. HARRISON, M.D.

THE opinions of the medical profession with regard to the value of the curette have been widely at variance from the time it was first devised to the present day. By some extolled as of inestimable utility, by others it has been decried as an instrument excessively hazardous in its application. Thus Aran,† in speaking of the use of the curette, calls it "cette pratique hasardeuse." Becquerel ‡ says: "This means (*rachement*) has always seemed to me barbarous."

Scanzoni § observes that "the curette recommended by Récamier and Sims for the abrasion of granulations developing in the uterine cavity is an instrument based on quite erroneous theories, and is therefore devoid of all practical utility." "We fully concur," he continues, "in the views of Hildebrandt when he says: 'Bad defects may be evoked in the sound portions of the uterus by these sharp-edged instruments, while the diseased portions remain intact; they do not, therefore, fulfill their proper purpose, with all the harshness of their action.'"

The language of Dr. Emmet || is equally positive in condemnation of this instrument. "As regards the instrument of Dr. Sims," he remarks, "I honestly believe that the ingenuity of man has never devised one capable of doing more injury. . . . I have known peritonitis, cellulitis, pelvic abscess, and even death, to occur on removing these growths from the uterine canal with a curette, and in every instance the operator was dexterous in the use of the instrument. My views are based on a dearly-bought experience, and I believe that no man has a right to place the life of his patient in jeopardy by the use of either of these instruments in the treatment of this condition."^ Dr. Sims, ^ on the contrary, when he so modified the original instrument of Récamier as to make it more effective and certain in application, considered that he had laid the profession under lasting obligations to him, and that no contribution he had made to gynecology was so important as his reintroduction into practice of the use of the curette. Dr. A. Martin, j of Berlin, in the concluding lines of his article upon intra-uterine treatment, gives this testimony to the value of the application of the curette: "From these observations of mine, I think that I am justified in urgently recommending the use of the curette in cases of morbid conditions of the mucous membrane of the body, whether they are connected with pregnancy or not. I consider this procedure as certain in its final result, as devoid of danger, and

not more circumstantial than certainty of success and freedom from danger demand."

In these circumstances it may not prove an altogether unprofitable study to examine the question anew, in the light of modern investigation and experience.

Our problem is twofold—first, to determine what affections of the uterus demand the application of the curette, and, second, to ascertain the best method of using it in an appropriate case. In 1846 Récamier devised an instrument that he called the curette for removing granulations from the cervical canal. The procedure he termed *curetage*. Four years later he modified the construction of his instrument, and extended its application to the removal of granulations, as well as portions of the ovum left after an abortion, from the uterine cavity. Simon made use of a similar procedure in the case of malignant neoplasms of the uterus, and invented an instrument like a spoon, with which his name is generally associated.

Dr. Sims, in his work, "Notes on Uterine Surgery," introduced to the profession a modification of Récamier's instrument, which can be bent so as to conform to the direction of the uterine cavity. Impressed with the dangers attendant upon the use of the Sims instrument, Dr. Thomas devised a further modification, which he calls the wire curette. This last instrument has been widely adopted into practice, and, especially in this country, is the form of curette most generally used. My own experience is mainly with Sims's curette and Thomas's. Simon's spoon I have only used in malignant growths. In attempting now the solution of the problem first propounded, it is necessary to appeal to analogous affections in other parts of the body, and the surgical procedures adopted for their relief, to give us a basis on which to rest our therapeutical principles. Says Prowchonic: * "We make use of these abrading and scraping instruments, so-called sharp spoons (essentially like curettes, and therefore often so called, and still oftener applied in place of them), for the removal of soft, spongy masses, whether in the form of tumors or purely granular, which have formed themselves pathologically on a normal, or at least almost normal, anatomical base, skin, muscles, fasciæ, glandular walls, bony cavities. Surgery teaches us, also, that these particular instruments form at the same time the best guide to the recognition of the boundaries of such destructive masses, taking away in their application nothing from the normal basis-tissue, and manifesting to our sense of feeling, sometimes also to the sense of hearing, although the field of operation may not be made accessible to the eye, when we have attained to the normal basis-tissue. According to the analogy of its surgical use, the sharp spoon is indicated wherever a degeneration of the mucous membrane has exhibited itself on a normal, or almost normal, anatomical basis—that is to say, the uterine muscle—a degeneration of such a character as would prompt the surgeon, in other parts of the body, to the application of the sharp spoon, consequently, granulations, or new formations, whose transition into the normal tissue is not accurately cognizable to the eye, or feel of the finger, or instruments of another kind, but whose fundamental removal up to the normal basis

forms the therapeutic demand of the case in hand." The researches of Düvelius,* characterized as they are by scientific exactness, have fully shown, in the first place, that, by the energetic application of the curette, material can be obtained adequate to the purpose of microscopic diagnosis with respect to the morbid process taking place in the uterine mucous membrane. Secondly, that, when the curette has removed the degenerated uterine mucous membrane, out of the remains left behind a regeneration of the mucous tissue takes place, a new and healthy mucous membrane being formed by means of the young cells proliferating from the deeper parts; that cicatrices are not produced in consequence of the action of the curette. Thirdly, that *amenorrhœa* and *sterility* are not caused by the curette, and that, on the contrary, many women who had been formerly sterile have conceived after its application. Applying these principles to uterine affections, we may say that the use of the curette is indicated in the following morbid states of the uterine mucous membrane:

1. In *sarcomata* and *carcinomata* of the inner surface of the body of the uterus—when, for any reason, more radical operative procedures are contra-indicated—the use of the curette yields here very satisfactory results, though of a palliative character.

The hæmorrhage and sanious discharge may in this way be relieved for a considerable length of time. The Sims curette in this class accomplishes the object in view most effectively. In a case of round-celled sarcoma of a diffuse form, confined to the mucous membrane of the uterine body, I prolonged the life of a patient for several years by the repeated application of the Sims curette. In carcinoma involving the cervix, the curette has but a limited application, as other methods of treatment are here required.

2. In those puerperal conditions of the endometrium evoked by retention of the remains of the ovum or decidual membranes. When delivery has occurred at term, and symptoms during the puerperal state point to the retention of the placenta, or pieces of the membranes, it is not necessary, as a rule, to resort to the use of the curette. In such an event the patient can be put under the influence of an anæsthetic, and the finger may be passed into the uterine cavity, and the offending parts removed manually. Or we may resort to the use of irrigation of the uterine cavity with hot water, to which an antiseptic is added. In some rare cases, however, these methods may fail us, or be inapplicable, and then the curette comes into play, and especially Thomas's wire curette. In a case of secondary hæmorrhage occurring three weeks after delivery I resorted to the application of the curette, and, after removing some shreds of decidual membrane, had the gratification of seeing the hæmorrhage cease at once, and rapid involution ensue. A much wider field, however, for the curette opens when pregnancy is interrupted in the first three or four months. The manual removal of portions of retained ovum or decida in such circumstances may often be achieved, but it nevertheless occurs that this method can not be adopted. For example, the physician may be called some

time after the expulsion of the ovum, and find the uterus too firmly closed to admit the passage of the finger. There may also be considerable narrowness of the vulva and vagina, and the neck may be rigid and unyielding. The hot-water intra-uterine injections may also fail to detach the firmly adherent remnants. In these cases the wire curette subserves a most excellent purpose. As an illustrative case I may cite the following:

I was called the 1st of last September to see a young married woman, whom I found suffering from a profuse uterine hæmorrhage. She informed me that an abortion had occurred in the month of June, at about the third month of pregnancy; that at the time of its occurrence she had lost a great quantity of blood, and had since been scarce free from a show, and that at times the bleeding was so free as to make her entertain grave apprehensions lest she should bleed to death. A homœopathic physician had been in constant attendance upon her, but had not succeeded in controlling the hæmorrhage; on the contrary, according to her statement, he made no effort in that direction, as he said that it was necessary for the blood to come away. The patient was pale and exsanguinated, and exceedingly nervous. Examination *per vaginam* revealed the fact that the uterus was very much enlarged, and, consequently, was in a state of subinvolution. Assuming that the symptoms were due to retention of portions of the ovum, I made use of the wire curette of Thomas, and extracted several pieces—one as large as the end of the thumb. I need scarce add that the hæmorrhage was checked at once, and that involution afterward took place rapidly.

3. In the various forms of endometritis, especially those characterized by menorrhagia and metrorrhagia, in which the degenerated mucous membrane has given rise to fungous granulations, the scope of the curette's application is here an extensive one. The pathological anatomy of chronic endometritis has lately been made the subject of thorough investigation by Ruge.* A condensed statement of his researches may not be uninteresting. The mucous membrane in chronic endometritis is, according to him, more or less strongly proliferated, vascular, soft, and spongy. The thickness is three to four millimetres, but may even attain to the thickness of a centimetre, nay, even exceed it. The inner surface of the mucous membrane, looking to the cavity of the uterus, is often smooth in spite of active proliferation; in other cases slightly papillary, like velvet, or elevated in the form of protuberances, proliferated to irregular rolls, or even polypoid outgrowths. The uterine cavity is often filled up completely by these spongy masses. Microscopically, the different forms of chronic endometritis are to be discriminated, according to their anatomical composition, into *glandular*, when the proper parenchyma of the mucous membrane, the glandular apparatus, is concerned; into *interstitial*, when the stroma plays the chief rôle, and into the *mixed forms*. The glandular endometritis is distinguished by a strong proliferation, and multiplication of the epithelial cells. There are two varieties, *glandular hypertrophic endometritis*, and *glandular hyperplastic endometritis*. In the interstitial endometritis the pathological changes are to be found in the stroma it proliferates, so that in the more recent cases proliferation of the cellular constituents is

* "Zeitschrift für Geb. und Gynäk., Bd. x, Heft 1.

* See Schröder's "Krankheiten der weiblichen Geschlechtsorgane," p. 111.

more apparent; in the older ones, the framework, the intracellular substance exhibits the pathological alteration. In the mixed forms (endometritis diffusa) the inflammatory process affects all the parts, although not uniformly. Olshausen's chronic hyperplastic endometritis (endometritis fungosa) he regards as varied in its composition. The proliferation of the mucous membrane, that can here assume the greatest dimensions, is generally diffuse, but may be an almost purely interstitial form, so that the glands are widely separated by the strongly proliferated stroma, and at the same time become primarily and secondarily ectatic; in another case the affection is a purely hypertrophic glandular, no multiplication of the glandular ducts taking place, although a great enlargement of the entire glandular duct necessarily went hand in hand with the proliferation. There can also be an actual hyperplastic glandular endometritis, an actual multiplication of the glandular ducts. The most important symptom of chronic endometritis is hæmorrhage, typical or atypical. In some forms dysmenorrhœa is complained of.

In another class of cases the pain is absent during menstruation, but appears in the middle of the free interval. Other women complain of a constant pain which undergoes exacerbation during menstruation. In still another class, women are free from pain during the flow, only to have it recur when the flow has ceased. Sensibility of the uterine mucous membrane to the contact of the sound is also characteristic of endometritis. Sterility is a frequent consequence of this affection. The effect on the nervous system is shown by a train of well-known symptoms, not necessary to be here enumerated. *A priori* considerations, derived from the study of the pathological anatomy, would naturally raise doubt as to the efficacy of vaginal and intra-uterine irrigation, or cauterization, in effecting a restoration of the uterine mucous membrane to a healthy standard, and experience of competent observers has fully shown how little reliance can be placed on these methods. The indication of treatment is obviously to thoroughly remove the degenerated mucous membrane, so that the mucous membrane, forming anew, may remain normal under appropriate treatment. The curette enables us to satisfy this indication fully, especially when its use is followed by injections of iodine into the uterine cavity. Sims's curette is the form of instrument I have generally used, although, when the fungous growths were exceptionally soft, I have found that Thomas's wire curette accomplished the purpose satisfactorily.

4. In those small, benign neoplasms of the mucous membrane of the body of the uterus that are still confined in their growth to the uterine cavity—such as mucous and fibrinous polypi and adenoid growths. The application of Sims's curette, especially, can here effect the ablation of these small neoplasms with certainty. Dr. Emmet's curette-forceps can also be used advantageously in these cases.

5. In the secondary endometritis of areolar hyperplasia (chronic metritis), and in the endometritis complicating myoma uteri. The application of the curette in these circumstances is a limited one. The procedure is especially dangerous in the case of myoma, as, in consequence of an interference with its nutrition, the myoma may suffer necro-

sis and undergo putrefactive decomposition, if infectious matters have been introduced into the uterine cavity. Thomas's wire curette, however, in this latter form of endometritis, has afforded excellent results, in my hands, in a number of cases.

Lastly, the curette is applicable for diagnostic purposes; when abnormal secretions and hæmorrhages indicate a morbid condition of the uterine mucous membrane, the curette is the most certain and simplest means of making an exact diagnosis. Our second problem, as we saw above, relates to the best method of performing the operation. The principles that should guide us in its selection are those that obtain in every other surgical procedure, and may be summed up in the apothegms: a careful preliminary preparation of the patient, a strict observance of antiseptic precautions, carried out to the minutest details, and a judicious after-treatment. In the practical application of these principles, the patient should be instructed to use vaginal douches of an antiseptic solution for some time previous to the performance of the operation. The time selected should be preferably soon after menstruation. The patient must be placed upon a suitable table, and, if she is nervous and lacking in courage, an anæsthetic should be employed; whether she should lie on her back, or be put in Sims's lateral semi-prone position, will depend on the convenience of the operator.

The first is to be preferred when the uterine walls are thin and flabby, and it is necessary to control the movements of the curette through the abdominal walls. The anterior lip of the os uteri is seized with a tenaculum, and, unless already sufficiently open, the cervical canal should be dilated by the introduction of steel sounds (or Hegar's hard-rubber dilators) passed in succession until the proper degree of dilatation is effected. Before and after the application of the curette the uterine cavity should be thoroughly disinfected by an intra-uterine injection of an antiseptic solution; without the expenditure of much force, the curette scrapes the anterior wall, then the posterior, and afterward the lateral angles. By giving it the proper curve, it may easily be applied in each horn where the tubes pass off, and here especially we are apt, in chronic endometritis, to find fungous growths in excess. The diseased portions of the mucous membrane manifest themselves by their peculiar softness, as a rule. After this operation the patient should keep her bed for four or five days. As regards the question of danger in the application of this procedure, Hegar and Kaltentach* use this language: "In a very great number of cases we have never yet seen an injury from the use of the curette, and consider the procedure, applied in conformity with proper indications, as one of the most satisfactory in operative gynaecology." "This method of treatment," remarks Schroeder,† "is free from danger if undertaken with painstaking observance of antiseptic precautions. Among many thousand applications of the curette and injections in simple chronic endometritis, I have, indeed, seen exacerbations of existing perimetritic inflammations ensue, but scarcely ever fresh inflammatory phenomena. One case

* "Die operative Gynäkologie," 2te Aufl., S. 506.

† "Die Krankheiten der weiblichen Geschlechtsorgane," 6te Aufl., S. 124.

of death from infection, to be sure, before the antiseptic time." In these views I heartily concur, my experience leading to like conclusions.*

FRACTURE OF

THE FLOOR OF THE ACETABULUM.†

By CHARLES C. F. GAY, M. D.,

BUFFALO.

SURGEONS concede the difficulty, if not impossibility, of recognizing this fracture. There are no symptoms, except pain, indicative of this lesion; hence writers affirm that its presence can only be suspected. Furthermore, it is believed this fracture rarely exists, and that when it does occur it is caused by violent, rather than slight, blows over or upon the great trochanter.

Observation of cases of hip injury in hospital and private practice, examination of cabinet specimens, dissection, and limited experiments upon the cadaver, have led me to conclude that this lesion occurs much oftener than has hitherto been supposed, and that great violence is not an essential element in its causation.

Unable, as I am, to indicate any new sign of the presence of this fracture, and since nothing more than rest can be advised for patients with suspected acetabular fracture, it would seem a waste of time further to agitate the subject; but, having seen cabinet specimens of union of this bone, when, during life, fracture had not been recognized nor knowledge obtained of serious injury, I am impressed with the importance of calling attention to the subject, and suggesting the possibility that slight causes may produce the injury, that it is not so rare as we may have believed, and to warn against the danger arising from too frequent examination and unnecessary manipulation, in order to establish the nature of the lesion.

When fracture occurs at the floor of the acetabulum, the floor may be traversed by a single fissure, or the line of fracture may run in a semicircular direction, or it may be angular and the bone resolved into its three primitive pieces, which, according to authors, is a very rare fracture. Sir Astley Cooper reports a case, Sanson one, and Neill another, and these cases are referred to by Erichsen, Hamilton, Agnew, and others, because they are rare. Other cases have been reported of the same kind with recovery, or in which bony union has occurred without displacement.

Fracture of the floor of the acetabulum may occur alone or be associated with fracture of the innominate bone. It may take place with or without displacement of the head of the femur.

This subject requires me to consider briefly the *structure and construction* of the acetabulum. The anatomist informs us that the thinner parts of the bone, as at the floor and

center of the iliac fossa, are composed entirely of compact tissue.

The cavity may be divided into three component parts. At its deepest part the bone is so thin that it transmits light; it is so frail that it is strange it should so often escape fracture; but the upper and posterior portion is formed by the thickest and strongest part of the os innominatum, and is capable of bearing great weight and resisting immense force.

The acetabulum is partly articular, partly non-articular. The articular portion is of horse-shoe shape. It is altogether deficient at the cotyloid notch, which corresponds with the gap of the horse-shoe.

The non-articular part extends from the cotyloid notch as a rough recess in the floor of the acetabulum, and corresponds to the area inclosed by the horse-shoe.*

This is a wise provision in the construction of this cavity, since in this way the thin portion of bone is measurably protected from violence. Were the thin and delicate portion of the acetabulum in apposition with the head of the femur, it would not be possible, without fracture, to resist violence or withstand even the weight of the body. By this peculiar and wise anatomical arrangement the deeper portion of the cavity is protected against the inroads of friction, while at the same time it is an element of weakness as regards any provision against injury from undue force or pressure. It is easy to conceive how the impact of strong and violent force which would drive the head of the femur against the circular and projecting rim of the articular portion of the cavity may cause fracture of the thinner, without fracture of the thicker, portion of the bone.

The ease with which this bone can be fractured may be shown upon the cadaver. Place a piece of sole-leather over the trochanter to protect the soft parts, then strike in an oblique direction upward with a mallet, and you will fracture either the neck of the femur or the floor of the acetabulum. Fracture of the floor of the acetabulum may occur at any age, but it is most likely to occur in the young subject, and without the application of much force. Take the case of a man who falls—perhaps but a short distance; he strikes upon the trochanter; he lies helpless, or, it may be, is able to rise; he complains of pain, and thinks he may have fractured his hip; the pain is aggravated when any attempt is made to move; he is assisted to bed; is subjected to repeated examinations without disclosing any injury save slight contusion of the soft parts. There is no shortening or eversion of the limb, nor crepitus. The patient occupies his bed for two or three weeks, gets up and walks about the room with the aid of crutches, and in two or three weeks more is able to go about without support. The injury has apparently resulted in nothing except it be acetabular coxalgia. There is no deformity. What could have been the nature of an injury causing such persistent pain? Was it possible to ascertain its nature? Was the pain caused by contusion of the soft or hard parts? No. Had he intra- or extra-capsular or mixed fracture? No. It perhaps ought to be suspected that the lesion was a fracture of the floor of the acetabulum without displacement of the head of the femur.

* In order to avoid all misunderstanding, it may be well to state that I regard as contra-indicating the application of the curette any recent inflammatory process in the vicinity of the uterus, such as perimetritis, parametritis, oöphoritis, and salpingitis. Retroflexion of the uterus, especially if complicated by perimetric adhesions, would demand great caution in its use.

† Read before the New York State Medical Association, November 19, 1884.

* Morris.

This is a type of cases which fall under the observation of every surgeon, the *diagnosis* of which is very difficult to make out. The two following cases—one a case of Dr. Sands's,* the other my own case—illustrate the difficulty experienced in diagnosing this lesion.

Dr. Sands styles his case a "perforating fracture of the acetabulum."

The patient, aged sixty-six years, had fallen in a dumb-waiter well. When first seen, the patient was suffering severely. In forty-eight hours after the injury Dr. Sands noted the facts already observed by Dr. Levings, viz.: That the limb was not shortened nor everted; that the heel could be elevated; the limb was capable of free rotary motion; the trochanter described the arc of a circle, and there was *no crepitus*. Autopsy revealed the fact that the head of the thigh bone had penetrated the floor of the acetabulum, and that there was fracture of the pelvis.

My own case is reported by Dr. McBeth, house surgeon.

Ella Smith was brought into hospital April 26, 1880; single, American. Had been the mother of one or more children; contracting syphilis in September, 1879. Six hours previous to entering hospital she had fallen from a veranda to the pavement, a distance of thirteen feet, striking upon her right hip. Dr. Frederick and myself [Dr. McB.] gave her ether and made an examination, finding slight eversion of the toe, and crepitus. There was no shortening, each limb measuring thirty inches and a half. We did not consider a diagnosis of intra-capsular fracture positive, but, as relief was afforded by extension, we put on extension with eight-pound weight.

April 27th.—Patient seen by Dr. Gay, who made an examination and carefully measured the limbs, finding them same as night previous. Patient stated to-day that the eversion of toe was natural, having had it from childhood. There was *no crepitus*. Dressings by extension were therefore discontinued, thus allowing muscular action to shorten the limb if there was fracture.

May 5th.—This is as early as it was deemed advisable to make further examination, on account of dysmenorrhœa from which the patient suffered. She was etherized, and another examination made. The injured limb measured a trifle longer than the limb of the sound side; there was no more eversion and no crepitus. As the patient was somewhat relieved of pain by slight extension, Dr. Gay advised its continuance with use of eight-pound weight. For a time after this she was in a typhoid condition, and evidently suffering from septicæmia, having chills with fever, temperature reaching as high as 105° F. Tenderness over caput coli, and abdomen tympanitic. She sank gradually with little pain, and died May 19th. Rapid post-mortem changes. *Autopsy May 20th*; present Drs. Gay, Diehl, Peterson, and Frederick. In cutting down upon the hip, found large quantity of pus evidently from the abdominal cavity, as it could be forced through the opening in hip by pressure over abdomen. Vagina filled with pus. Found fracture of the acetabulum in three directions following the original line of union, involving fracture of innominate bone.

There is no sign in either of these reported cases that could possibly suggest the lesion revealed by dissection; therefore they confirm the correctness of statements made by writers. My house surgeon thought he detected crepitus when the patient was first examined, but crepitus was not found to exist at the examination made the next morning.

It is easier to presume he was mistaken than to believe that crepitus existed. If crepitus is ever observed, it must be in consequence of co-existent fracture of the innominate bone.

"There are no signs clearly distinctive of this fracture."* If fracture of this bone can only be suspected, then diagnosis of this lesion has for the first time to be made.

There is no shortening, no eversion, no crepitus, whether there be displacement of the head of the thigh bone or not; but there is pain in the hip which is aggravated by movement of the joint, by pressure upon the trochanter, and by attempts to turn the patient upon the side. I have said that pain is the only sign of this fracture; it exists with equal severity with that which accompanies fracture of the cervix femoris, but without the evidence of fracture the latter reveals. Therefore severe and persistent pain, in the absence of positive symptoms of fracture, is a sign of some significance of this lesion. Explorations through the rectum or vagina may assist in determining the nature of the injury.

Prognosis.—Fracture of the acetabulum without displacement of the head of the thigh bone does not constitute a fatal, nor even dangerous, injury, provided the lesion be early suspected and the patient let alone. Fracture with displacement is not necessarily fatal, as may be shown by the following remarkable case under the care of Charles Hewitt Moore,† of Middlesex Hospital. This is the case I supposed referred to by authors:

James Thomas Horsfield, who died at the age of sixty, was crushed about the pelvis, several years before, by a piece of timber. The left limb was shortened, and its principal motions were abduction and moderate flexion, while circumduction and extension were impossible. Dissection of pelvis: left innominate bone broken in the acetabulum into three pieces, corresponding to its original segments. These pieces were separated by the head of the femur having been driven through them into the cavity of the pelvis, where it rested upon the sacrum, below the promontory. The trochanter had worn a new socket upon the brim of the acetabulum. The right innominate bone was broken just in front of the acetabulum. Both ischio-pubal rami were broken. None of the fractures had united with ossific matter. Owing to this fact and to the fact that the pubes had been separated from all connection with the main body of the pelvis, the former (pubes) was displaced upward (possibly by muscular action) and backward, thus materially narrowing the pelvis antero-posteriorly. The pubes was also displaced laterally, i. e., somewhat twisted. As the person, in walking, bore most of his weight upon the right thigh, the corresponding ilium, which had now no support from the pubes, became bent toward the spinal column.

If recovery be possible under adverse conditions such as report of this case reveals, no one need hereafter despair of recovery in any case.

Treatment.—But little can be said upon the subject of the management of these cases. The surgeon wants less to know what to do than what not to do. Meddlesome surgery can not be advised. Rest of the joint is of the first importance. Whenever, therefore, a fracture is not made out, but is suspected, the patient should be let alone as much as possible, the limb left to rest in an easy position, with or without moderate extension, according as it is

* "Med. Record," vol. xii, 1877, p. 93.

* Agnew.

† "Med. Times," vol. ii, N. S., p. 384.

grateful or otherwise to the patient. In the case I have reported, it is quite probable the patient was deprived of her only chance of recovery by repeated examinations, two of which were entirely unnecessary, since they inflicted injury, without leading any nearer to a correct diagnosis.

Correspondence.

LETTER FROM WASHINGTON.

The National Conference of State Boards of Health and its Bill for the Establishment of a New National Board of Health.—The Bill for a New Museum and Library Building.

WASHINGTON, December 15, 1884.

The principal event of the week has been the meeting of the representatives of State boards of health, which convened, pursuant to adjournment, in this city. The conference drew up a bill which, if it becomes a law, will reorganize the National Board of Health, or rather establish a new one. This board will consist of persons appointed from actual State boards of health, and no person not at the time a member of a State board of health is to be eligible for appointment. No compensation is to be charged for the services rendered, but actual necessary expenses will be allowed. The duties of the board are to be, to investigate the causes of diseases and epidemics at home and abroad, to make regulations for quarantines, and to aid State boards of health. The former laws relative to vessels from infected ports are to be re-enacted, and the several rules and regulations, when duly approved by the President, are to be executed by the existing departments of the Government. The board is to have a chairman and a secretary, and is to meet annually; it may, however, be called together in a sudden emergency by the President of the United States, or by its own officers. The Department of State is hereafter to prepare the abstracts of the information received from consuls and medical officers abroad, and transmit the same to persons officially interested. Five hundred thousand dollars are to be appropriated for the purposes of the act.

It is thought, by those interested in the measure, that the practical working of the new bill, which may possibly pass at this session of Congress, will remove the sources of irritation which were found under the operation of the old law. The new board will have the special advantage of representing something, will constitute a powerful organization, and, as it will be legislative and advisory in its functions, will meet with no opposition from the departments of the Government whose duty it will be to carry its decrees into effect. The work of sanitary investigation will certainly suffer no diminution in vigor by being placed in the hands of practical men. The result, while perhaps mortifying to the present board, will harmonize other conflicting interests, and can meet only with success. The only drawback to the passage of the bill at this session is the fact that the latter is short, its real business requiring to be accomplished in less than two months.

The bill for the erection of a new museum and library building is expected to come up this week, and, as there is no opposition, its friends look confidently for its passage.

On the last day of the session of the Committee on Federal Legislation of the Health Conference, its members were entertained by the Health Officer of the district with an "oyster roast" at one of the wharves. Several influential members of Congress assisted in hiding the bivalves from mortal view, and hilarious speeches were made. As a legislative persuader the oyster has an established national reputation; it might be said, *Per ostrea est iter ad appropriationes*. However that may be, the entertainment was as successful as it was unique, and everybody concerned was happy.

NEW YORK, SATURDAY, DECEMBER 20, 1884.

MEDICAL REFORM.

WE have received copies of two excellent addresses, one of which, on the "Legal Control of Medical Practice by a State Examination," was read by Dr. John B. Roberts before the Medical Jurisprudence Society of Philadelphia. The other, entitled "A Discussion of Some of the Questions of Medical Education and Medical Ethics," was presented to the Philadelphia County Medical Society by Dr. Henry Leffmann. The topics touched upon in these papers are so important that we can not forbear commenting on some of them.

Dr. Roberts handles his subject ably, and the plan which he suggests would, if adopted, doubtless work a radical change in the character of the medical profession. He advocates the establishment of a State board of medical examiners, "which shall examine all persons desiring to enter upon practice in this State [Pennsylvania] after January 1, 1886, without regard to when, where, or how they obtained their medical education." He does not aim at abolishing either the courses of instruction or the privileges of the schools, but suggests that a State examination, and not the simple presentation of a diploma, should be the prerequisite to registration. He maintains that, under the system he outlines, not only will the examinations be strictly impartial, but able men who may have been unjustly rejected by the schools, and incapable students who have been let through, will have their qualifications more carefully tested. We fancy there will be little dissent from the general truth of the view taken by Dr. Roberts, but the satisfactory arrangement of the details does not seem easy of accomplishment. In February a committee is to report upon the subject to the Medical Society of the State of New York, and it may turn out that that committee has been able to solve the knotty problems connected with it. At all events, we hope that the matter will be discussed thoroughly when the committee has made its report, and we therefore refrain from its further consideration at present.

Dr. Leffmann's essay is elaborate and forcible, but with one of his suggestions, which he terms a "radical improvement," we are inclined to think that he will find he is running counter to the fixed sentiment of the profession—a sentiment that we take to be decidedly well founded. His proposition is to encourage the student to work in a special direction after a single year of general medical study. The establishment of separate degrees in the individual branches of medicine is novel, but the idea does not seem to us commendable. Were this system to be adopted, the country would soon be overrun with uneducated specialists, and there are too many of them already. A separate degree in medical jurisprudence, as suggested by Dr.

Brouardel, is not so objectionable; in fact, there are good reasons why special instruction should be given in this department, but let such a course supplement a thorough general training, and not take its place.

Another matter in which we can not agree with Dr. Leffmann is his proposal to throw out of consideration entirely the time spent by the student in private study with a practitioner. This, we fear, would work great injustice, at least in the present condition of our country, to many poor and worthy young men whose circumstances prevent them from spending three full years in a medical school; certainly, if it had been enforced years ago it would have excluded many of the present leaders of the profession. We are not yet prepared to regard the preceptor's certificate as of no value, but we do think that the student whose first year has been spent in office study should be required to pass the same examination as the class which he proposes to enter—a rule that is adhered to rigidly by academic institutions.

MINOR PARAGRAPHS.

A DELICATE SUBJECT FOR A NOVELIST.

THE "Gazette hebdomadaire de médecine et de chirurgie" reviews at length a new novel with the suggestive title of "*Le faiseur d'hommes*." The romance is nothing more nor less than a plea in favor of artificial impregnation; the *dramatis personæ* are a childless count and countess and a highly scientific physician. A certain abbé is also introduced, in order to fill out the religious side of the picture. Not to enter into the details of the subject, which are better suited for a treatise on gynecology than for a popular novel, it suffices to say that the experiment is successful, the result being a son, who is afterward known at Court as the "child of the syringe." But the most curious reading is the long and abstruse argument against artificial impregnation which the reviewer introduces into his article. We can liken it to nothing but the discourse on the seven deadly sins ascribed by Chaucer to his parson in the "Canterbury Tales." In fact, the writer's view of the subject from a medical standpoint is scarcely less fanciful than the novelist's.

SANITARY WORK IN BROOKLYN.

THE Brooklyn Health Commissioner, Dr. J. H. Raymond, having been asked to submit to the recent conference of representatives of State and municipal boards of health an account of what was being done by the sanitary authorities of that city to place it in a proper condition to meet the probable advent of cholera next summer, has presented a very forcible statement, in which he discusses both the matter of quarantine and the local conditions that need to be looked to. It appears that a great deal has been accomplished already toward putting the city in an improved sanitary state, and that, from Dr. Raymond's showing, the machinery is very well arranged for carrying on the work to the necessary extent.

THE CHOLERA CONTROVERSY IN GERMANY.

FINKLER and Prior have addressed a communication to the "*Kölnische Zeitung*," resenting the imputations which Koch has made on their skill in bacteriology. The excuse they give for stating their grievances in a newspaper is that they wish their views to be more widely known than they could be from their publication in a medical journal. The "*Deutsche Medi-*

zinal-Zeitung" comments upon the bad taste displayed by them in the matter, and suggests that, if they wish to "save their professional honor," as they allege, it would be more dignified to address themselves to the profession than to the general public.

PROFESSOR SCHWENINGER.

It appears that this individual, who was arbitrarily placed by Bismarck in the chair of dermatology at the University of Berlin, persists in holding the position in spite of the opposition, amounting to ostracism, shown by his indignant colleagues. We learn that his clinic has not been honored by the presence of a single student. Although the Government has been able to force an unworthy candidate upon the institution, it is powerless to inspire respect for a man who is small enough to be the agent of despotism.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following statement of cases and deaths reported during the two weeks ending December 16, 1884:

DISEASES.	Week ending Dec. 9.		Week ending Dec. 16.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	19	14	32	7
Scarlet Fever.....	60	13	101	21
Cerebro-spinal meningitis...	3	3	5	3
Measles.....	126	20	147	19
Diphtheria.....	73	40	76	32

The New York Orthopædic Hospital and Dispensary.—This excellent institution derived substantial aid, we are happy to learn, from the proceeds of an entertainment given in its behalf at Delmonico's last Saturday afternoon.

The Manhattan Eye and Ear Hospital.—We are glad to learn, from the Fifteenth Annual Report, that this institution is now entirely out of debt. It is supported by voluntary contributions, and is intended for the free treatment of persons who are too poor to pay for medical advice.

Local Health Officers in the State of New York are hereafter to be appointed only after a competitive examination, in accordance with the new civil-service rules. The examination papers are to be prepared by an examining board of five physicians, to be designated by the Civil-Service Commission, and the examinations are to be held in the presence of a county judge, who will transmit the papers to the Commission.

The Buffalo Obstetrical Society.—At the next meeting, to be held Tuesday evening, the 23d inst., Dr. Thomas Lothrop is to read a paper introducing a discussion on "Rest during the Menstrual and Puerperal Periods."

The Paris Academy of Medicine, we learn from the "Gazette hebdomadaire de médecine et de chirurgie," has elected M. Charpentier, the obstetrician, to membership in place of the late Dr. Fauvel.

The Ninth International Medical Congress.—At the outset of its work, the General Committee of Organization has met with a serious loss in the death of one of its members, Dr. James G. Thomas, of Savannah. In a circular announcing the fact, the Executive Committee state that Dr. Thomas, at considerable sacrifice, went to Washington on the 29th of November, to attend the meeting for organization, and that on the way he was seized with pneumonia, which was the cause of his death.

The Death of Professor J. B. Fonssagrives is announced in the French journals. He was a well-known writer on various subjects connected with medicine, especially hygiene. He died of cholera.

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 7, 1884, to December 13, 1884:*

HAMMOND, JOHN F., Colonel and Surgeon. Retired from active service, by operation of law, on December 7, 1884, under provisions of act of Congress approved June 30, 1882. S. O. 287, A. G. O., December 8, 1884.

McKEE, J. C., Major and Surgeon. Leave of absence still further extended one month. S. O. 288, A. G. O., December 9, 1884.

PORTER, JOSEPH Y., Captain and Assistant Surgeon. Sick leave of absence extended four months on surgeon's certificate of disability. S. O. 286, A. G. O., December 6, 1884.

KANE, JOHN J., Captain and Assistant Surgeon. From Department of the East to Willet's Point, New York. S. O. 286, A. G. O., December 6, 1884.

BANISTER, J. M., Captain and Assistant Surgeon (Fort Adams, Rhode Island). Granted one month's leave of absence on surgeon's certificate of disability. S. O. 251, Department of the East, December 9, 1884.

GRAY, CHARLES C., Major (retired). Died at Geneva, N. Y., November 22, 1884, instead of November 26, 1884, as heretofore announced. Circular Orders, A. G. O., December 8, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending December 13, 1884:*

CRAIG, T. C., Passed Assistant Surgeon. Detached from the Alliance and placed on waiting orders. December 6, 1884.

CURTIS, L. W., Assistant Surgeon. Ordered to the Naval Hospital, Chelsea. December 9, 1884.

GAINES, J. H., Passed Assistant Surgeon. Present duty continued.

GREEN, E. H., Passed Assistant Surgeon. Ordered to special duty at Museum of Hygiene, Washington. December 11, 1884.

MURRAY, J. M., Passed Assistant Surgeon. Detached from Naval Hospital, Chelsea, and ordered to the Flagship Hartford. December 9, 1884.

WOOLVERTON, T., Surgeon. Ordered to the Shenandoah. December 6, 1884.

Society Meetings for the Coming Week:

MONDAY, December 22d: Medical Society of the County of New York; Boston Society for Medical Improvement; Cambridge, Mass., Society for Medical Improvement; Lawrence, Mass., Medical Club (private).

TUESDAY, December 23d: New York Dermatological Society (private); New York Surgical Society; Buffalo Obstetrical Society; Medical Society of the County of Lewis, N. Y.

WEDNESDAY, December 24th: New York Pathological Society; American Microscopical Society of the City of New York.

THURSDAY, December 25th: Harlem Medical Association of the City of New York; Roxbury, Mass., Society for Medical Improvement (private).

FRIDAY, December 26th: New York Clinical Society (private); Yorkville Medical Association, New York (private); New York Society of German Physicians (private).

SATURDAY, December 27th: New York Medical and Surgical Society (private).

The Charges against the President of the Academy of Medicine.—Charges having been preferred against the President of the Academy of Medicine, Dr. Fordyce Barker, by Dr. E. S. F. Arnold, Dr. Nathan Bozeman, Dr. Austin Flint, Jr., Dr. S. S. Purple, Dr. C. S. Wood, and Dr. William Young, turning upon the allegation that he was not a graduate of the Paris School of Medicine, as he had sworn to being, the testimony for and against the charges was investigated by the Committee on Ethics, consisting of Dr. Andrew H. Smith (chairman), Dr. Virgil P. Gibney, Dr. Charles A. Leale, Dr. Henry E. Cramp-ton, and Dr. C. Dixon Varley, and at the last regular meeting of the Academy, held on Thursday evening, December 18th, the committee unanimously reported (giving the evidence in full) that the charges were not sustained. On motion, the report of the committee was unanimously accepted and adopted by the Academy. On resuming the chair, which he had vacated during the reading of the report, Dr. Barker said: "Here endeth the second lesson." The Academy will now resume its scientific work, which it has continued zealously, efficiently, and harmoniously for thirteen months, until the present interruption by this supreme effort to elevate the character of the medical profession." Various motions were then made, looking to the censure of the gentlemen who had brought the charges, but, when it had been moved by Dr. John C. Dalton, supported by the President, that they be laid on the table, they were all withdrawn.

Changes in the German Faculties.—The "Progrès médical" learns that Dr. A. Gad, of Würzburg, has been appointed director of the Berlin Institute of Experimental Physiology, in place of Dr. Kronecker, who has been called to Berne.

The Death of Dr. Frederic Elliot, of New York, is announced to have taken place at Nyack on Wednesday, the 17th inst., at the age of fifty-six. Dr. Elliot was of English birth, but came to this country at an early age, and took his medical degree at the College of Physicians and Surgeons in 1851. He was a member of the Medical Society of the County of New York, of the Pathological Society, of the Physicians' Mutual Aid Association, and of the Medico-Historical Society. He was highly esteemed as a man and as a practitioner.

The New York Medico-Legal Society elected the following-named gentlemen to office at the annual meeting held on Wednesday evening of this week: Dr. R. Ogden Doremus, President; Clark Bell, and D. C. Calvin, Vice-Presidents; Leicester Holme, Secretary; J. S. McIntire, Assistant Secretary; M. Ellinger, Corresponding Secretary; Dr. J. A. Irwin, Treasurer; Dr. A. H. Smith, Curator; Dr. C. A. Doremus, Chemist; Dr. M. J. B. Messemer, Librarian; Dr. R. B. Kimball and Dr. E. Bradley, Trustees; and David Dudley Field and Dr. Stephen Smith, members of the Permanent Commission.

Letters to the Editor.

THE DISCOVERY OF THE ANÆSTHETIC PROPERTY OF COCAINE.

133 EAST THIRTY-EIGHTH STREET, NEW YORK, December 5, 1884.

To the Editor of the New York Medical Journal:

SIR: In the various articles on cocaine that have appeared in the many journals since its introduction as an anæsthetic, errors have been observed which I wish by this letter to correct. My authority for these corrections is contained in a letter received

the past week from Dr. Carl Koller, of Vienna, the discoverer. 1. It has been repeatedly stated that he was a medical student, whereas he is a graduate and assistant physician to the Vienna General Hospital. 2. It has been stated that cocaine had been used in Vienna by the laryngologists first, and that from them Dr. Koller conceived the idea of using it on the conjunctiva, whereas the converse is true. It is but just that due credit should be given to Dr. Koller for this wonderful discovery, which he arrived at by reasoning, and not by accident.

Very truly,

WILLIAM OLIVER MOORE.

Proceedings of Societies.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Meeting of December 4, 1884.

The President, Dr. R. A. CLEEMANN, in the chair.

Ovarian Tumor.—Dr. DRYSDALE presented a polycystic ovarian tumor which he had removed that morning. He had first seen the patient with Dr. C. R. Prall, May 5, 1884. She was married, fifty years of age, pale, thin, and delicate-looking. She had had eight children, the youngest of which was then sixteen years old. With some trifling exceptions, her menstruation had been perfectly natural until two months before; since then she had had a constant and sometimes profuse discharge of blood from the vagina, which still continued. She first discovered the tumor in March, 1884. On examination, Dr. Drysdale found a semi-solid, smooth-walled, globular tumor occupying the lower part of the abdomen and reaching nearly to the umbilicus. It was freely movable, did not fluctuate, but was elastic and a little tender on pressure. Vaginal examination revealed a lacerated cervix. The sound entered the uterus two inches and a half, taking a direction to the right of the tumor. On deep pressure, the end of the sound could be felt at the lower part of the right border of the mass. While the sound was in the uterus the tumor could be moved freely without affecting it. He diagnosed a multilocular ovarian tumor. By the 5th of June, one month later, it reached nearly to the ensiform cartilage. From this time it increased rapidly in size, and, when it was removed, filled the abdomen, pressing the lower ribs outward. It proved to be a multilocular tumor of the left ovary. His object in bringing it before the society was to obtain an opinion from the members as to the cause of a phenomenon which was observed in the early stage of the growth. When the patient first noticed the enlargement she found that, when she lay on her right side, the tumor, as if lighter than the surrounding parts, ascended to the left, and, when she lay on her left side, to the right. She informed Dr. Prall of this, and he naturally supposed she was mistaken; but a careful examination of the tumor while she changed her position verified her assertion. As the mass increased in size, this peculiar change of position ceased, and, when the abdomen was opened, nothing could be found to account for the singular behavior of the growth.

Hydrochlorate of Cocaine.—Dr. C. M. WILSON presented the histories of three cases in which the hydrochlorate of cocaine had been used with the hope of obtaining local analgesia, and reported negative results.

Malignant Cystic Disease of the Ovaries.—Dr. D. LONGAKER exhibited specimens with the following history: The subject was a German woman, sixty-three years old. She had been

married the last twenty-seven years of her life, and was sterile. During the last fifty months she had been under the care of Dr. Joseph S. Gibb, at whose request he first saw her and by whose kindness he was enabled to report the case. The menopause was established at fifty-three, ten years ago. The patient had always enjoyed fair health, but four years ago she again began to have a bloody discharge from the vagina. For this she consulted a doctor and was soon well again. The date of the onset of her last illness was indefinite. It was insidious, and the particular symptom for which she desired relief was inability to pass urine. This was found to be due to suppression, as the bladder was empty. There was also decided interference with nutrition. Her appetite and strength failed rapidly. The urine was found to contain a very small amount of albumin. She had occasional nausea, bilious vomiting, and diarrhoea. She suffered from pain in the left side of the abdomen. On examination, a hard, nodulated tumor was discovered, to the left of the uterus, projecting upward into the left inguinal region; it was adherent and but slightly movable. She was first seen by the speaker on October 6th. At that time she was in bed, suffered from orthopnea, and was unable to rest or lie down. Her abdominal cavity was greatly distended by a fluid which had accumulated rapidly in the previous three or four weeks. (Edema of the ankles had been noticed a few days before. Her general appearance was decidedly anemic and cachectic. The abdomen was very tender on palpation, especially over the left inguinal and hypogastric regions. The flanks were bulging and were flat on percussion. The tumor, which could be indistinctly outlined, was immobile, lying in contact with the left ilium, dipping down into the true pelvis, behind and to the left of the uterus and distinct from it. The cervix had undergone senile absorption, but from the os externum a small polyp was found hanging into the vagina. October 7th she was tapped, and a large bucketful of a brownish-red fluid, of the specific gravity of 1.020, was removed. On microscopic examination, it was found to contain blood and various corpuscles and epithelium. (The ovarian cell was not found). It contained paralbumin.

A more careful examination now revealed a circumscribed, clearly defined, firm, nodulated growth in the region already indicated. It was found adherent, and could be only slightly displaced. It was of the size of a large fist. Palliative treatment was continued, but the patient's condition gradually grew worse. There was again a slight accumulation of fluid in the abdominal cavity, she was subject to attacks of bilious vomiting, and diarrhoea alternated with constipation. There was no apparent increase in the size of the tumor, and during this period pain was not a marked symptom. At no time was there acute suffering. She died of exhaustion November 27th. At the autopsy, on the next day, by Dr. Gibb, in the presence of and assisted by Dr. E. W. Holmes and the speaker, the subcutaneous fat was found to have been almost entirely absorbed. The parietal peritoneum was covered with lymph, with numerous nodular elevations in various stages of organization. The intestines had contracted numerous adhesions. The capsule of the liver was one eighth of an inch thick. In the mesentery there were also deposits of lymph, some of which were more recent and less organized. The abdominal cavity contained about two quarts of fluid, the same as that already described. On the left side, extending two inches above the pelvic brim, was found a tumor, apparently solid, but which, on close examination, was found to be cystic. One of the largest of the cysts had ruptured; the opening was found at the posterior-inferior portion of the growth. It was not recent. The capacity of the emptied cyst was about four ounces. The tumor dipped down into the true pelvis, between the broad and utero-sacral ligaments of the left side. It was very adherent, and was removed with great diffi-

culty. On incising and freely opening the cyst, some coagulated fibrin was found, the remains of a hæmorrhage into the cavity. When it was entirely removed it was found to arise from the left ovary. The oviduct was slightly dilated, and its fimbriated extremity was adherent to and spread out over the tumor. On the right side, in the broad ligament, there was a cyst slightly larger than the tumor, its contents being dark and very dense. It was very heavy. The cyst was surrounded by a dilated Fallopian tube containing a clear, transparent fluid of a bluish-white hue. At its widest part it was an inch in diameter. Behind and below this cyst was found the right ovary, adherent, flattened out, and apparently continuous with it. The entire specimen was carefully dissected out as it was now shown. From its rapidly fatal tendency, with the macroscopic appearance of the tumor, there was very little doubt that a microscopic examination would show it to be malignant. Though perhaps possessing the greater pathological interest, there were also a few points in the case bearing upon diagnosis and treatment. Study of the fluid at first caused a suspicion that it came from a cyst; its high specific gravity and the chemical tests to which it answered favored such a view. But this was entirely at variance with the history of rapid accumulation and absence of the physical signs indicating the existence of a large cyst. It was apparent at the autopsy that an attempt at extirpation could only have hastened the fatal result. The specimen was referred to a committee for further investigation.

CHICAGO MEDICAL SOCIETY.

Meeting of December 1, 1884.

The President, Dr. D. A. K. STEELE, in the chair; Dr. LISTON H. MONTGOMERY, Secretary.

The late Dr. Abram Groesbeck.—Resolutions relative to the death of Dr. Groesbeck, an old and well-known physician, and an ex-president of the society, were introduced by Dr. R. C. HAMILL, and, after remarks by Dr. JOHN BARTLETT, eulogistic of the deceased, were adopted.

An Extensive Injury of the Face.—Dr. ROBERT TILLEY related the history of the case, and showed the patient, a boy about five years old, who had been injured by an elevator on the 23d of August. He was lying down on a floor, looking down into an elevator shaft, when the platform descended and struck him on the back of the head, just beneath the occipital protuberance, forcing the bridge of the nose against the edge of the opening in the floor. The resistance of the parts at the back of the neck and head being relatively great, very little injury followed in that situation, but the greater part of the force of the blow was sustained by the face, upon which the edge of the floor had evidently impinged, just at the junction of the frontal, nasal, and superior maxillary bones, producing a star-shaped laceration of the soft parts running up the forehead about an inch from the root of the nose, downward along the bridge of the nose for about the same distance, then upward along the right side of the frontal bone to a point corresponding to the outer end of the eyebrow. These wounds extended through the soft parts to the bone, and two others radiated downward and outward from the root of the nose. The nasal bones were crushed and in part destroyed, the soft parts were torn from the bones, and the cartilaginous septum of the nose was wrenched from the bony septum. The nose and adjacent parts hung down over the mouth and the lower lip, and it appeared as if the right eye was destroyed.

Absorbent cotton soaked in dilute acetic acid was packed in between the soft parts and the superior maxilla, on each side, to stop the bleeding, and the assistance of Dr. Charles Adams,

Dr. A. B. Hosmer, and subsequently Dr. C. T. Parkes, was procured. It was decided not to try to force the two maxillary bones closer together, but to leave the parts to heal by granulation, especially as it was thought that it would be difficult to anesthetize the patient. It was questioned, too, whether the advantage gained would equal the additional discomfort from any device that could be adopted. The boy was in a semi-unconscious state, but there did not seem to be any special indication of brain lesion. The soft parts were brought into good apposition with stitches, and both eyes were occluded with a pressure bandage. There was a good deal of œdema about the right eye. Slight fever followed at once and increased considerably on the fourth day, but yielded readily to the use of warm baths and a little calomel. Up to the time of the removal of the pressure due to the bandage there was persistent somnolence, but, when the bandage was taken off, the boy said, as if in answer to a question, "The elevator struck me." At intervals after this he told the circumstances of the accident, and called to mind various objects that he had seen in Dr. Tilley's office at the time the wounds were dressed. It was thought best not to reapply the pressure, and consequently the œdema increased, but union had taken place, except at the root of the nose, and all but two or three of the stitches were removed. Great swelling persisted, however, and subsequent interstitial suppuration made it necessary to reopen the superficial wound on the right side of the face and the superficial part of the deep wound on the left side. These two wounds were very obstinate in healing, and interstitial suppuration in the contused parts about the right eye had to be relieved by incision, which resulted in a scar at the malar prominence and the subsequent production of ectropion. The tendo oculi seemed to have been torn away from its attachment, causing the orbicularis palpebrarum to act at a corresponding disadvantage.

For nearly three months there was almost absolute anesthesia of the parts of the face implicated. There was marked diplopia, but it was evidently due to paresis of the muscles of the right eye, and the speaker thought there was no disturbance of the relative position of the two eyeballs. The paresis was now much relieved, and the anesthesia had almost disappeared, but the canaliculi were quite distorted, and it would probably be necessary to lay them open. The gap between the superior maxillary bones was completely closed, and the nasal passages had been almost occluded by adhesion of the inferior turbinated bones to the floor of the inferior meatus; but a passage had been forced through on each side with the galvanic cautery, and the boy's breathing and enunciation were now practically normal. It was proposed to remedy the ectropion and the general displacement of the right eyelids by loosening the cicatrix over the malar prominence as much as possible, and perhaps by making a counter-cicatrix on the inner side of the lid with the galvanic cautery; also to try to make a substitute for the disorganized tendo oculi by causing the integument to adhere to the bony structures opposite the inner canthus.

Dr. C. T. PARKES, who had seen the boy soon after the accident, thought that the result had been much better than could have been expected, in view of the terrible nature of the injury. Doubtless the measures which Dr. Tilley proposed would overcome the ectropion, which was the most prominent deformity that now remained.

Extra-uterine Pregnancy.—Dr. W. W. JAGGARD read a paper on this subject, in which he dwelt more particularly on the palliative measures to be adopted in cases of accidental rupture of the sac.

Dr. PARKES said that, according to his experience and his acquaintance with the literature of the subject, hæmorrhage was the chief cause of death in these cases, and he thought that

delay in the performance of laparotomy—the only means by which the hæmorrhage could be controlled—was expecting too much of nature.

Dr. J. H. ETHERIDGE alluded to a case of seven or eight years' duration, in which, the fœtus having become encysted, a trocar was finally introduced and the decomposed remains of the fœtus were discharged entirely.

Ovariectomy.—The PRESIDENT read the histories of three cases and showed the specimens. In one of the cases the patient did well for forty-eight hours after the operation, but symptoms of pyæmia then appeared, and she died on the fifth day. At the autopsy a small sponge, with a string attached to it, was found in Douglas's *cul-de-sac*, firmly imbedded in lymph. No hæmorrhage had occurred, but general peritonitis had set in, and the cause of death was quite apparent. But for the presence of the foreign body, the patient would doubtless have recovered, and it seemed almost impossible that it should have been overlooked when the final count was made. In the second case the operation was performed within a short time after an attack of peritonitis, and the patient did well. The third case was one of papillary cystoma; the patient recovered. The President wished to emphasize the following points: (a) Always count the sponges used in an operation; (b) observe absolute cleanliness; (c) peritonitis is not a contra-indication of either tapping or ovariectomy; (d) cystic fluid left in the peritoneal cavity is dangerous and likely to cause pyæmia, but blood is probably innocuous; (e) a rubber blanket fastened to the patient, with a central fenestra through which to operate, is useless, small tin basins for the waste being preferable, as they can readily be changed; (f) each case calls for special judgment and attention to every detail.

Laparotomy for Abdominal Tumors.—Dr. PARKES reported three cases—two of ovariectomy (successful), and one for uterine fibroma (with a fatal termination). There was nothing remarkable about the ovariectomies, but one of the cases was interesting from the fact that the patient came near losing her life by intestinal obstruction at the end of the third week. Such an occurrence was noteworthy, as serving to show that we should be on our guard against reporting "cures" prematurely. In the case of fibroma, supra-vaginal amputation of the uterus was performed. A solid rubber cord, a quarter of an inch thick, was thrown around the pedicle at the narrowest part, and drawn as tight as the operator's strength would allow; as a temporary ligature. The mass was then cut away about half an inch above the ligature, and hæmorrhage was seen to be wholly prevented, but, just as he had turned aside to place the severed mass on an adjoining table, and was about to take up the pedicle for further treatment, the rubber cord rolled over the free end of the stump, and the latter fell into the pelvis, out of sight, while the blood seemed to flow in torrents from its cut surface. Finally the stump was grasped between the thumb and fingers and drawn out of the pelvis again, and the bleeding ceased. The pedicle was then transfixed and tied in two halves. The trouble would not have occurred if a temporary clamp had been used. The pedicle was dropped, and in closing the external wound great difficulty was met with in returning the intestines within the abdominal cavity, and keeping them there while the sutures were tied. After rallying from the anesthesia, the patient vomited a great deal for a number of hours, and, after having ceased, the vomiting returned and lasted up to the time of her death, which took place forty hours after the operation. Only a very superficial autopsy was allowed; but this sufficed to show the cause of death to have been a gangrenous condition of about six inches of the ileum. The cause of this it was difficult to explain, for no twist had been found, and no noticeable injury was done to the gut at any time.

Both the President's cases and those related by Dr. Parkes being before the meeting, Dr. PARKES stated that he was present at the operation in which the sponge had been left in the abdomen, and that he remembered the precautions that had been taken to guard against such an accident. He admired the President's frankness in placing the case on record.

Dr. ETHERIDGE remarked, in regard to Drysdale's corpuscle, which had been mentioned in one of the cases, that it had been found in renal cysts.

Dr. R. G. BOGUE thought that it would have been strange if the patient had recovered in Dr. Parkes's case of supra-vaginal amputation of the uterus, so many and so great were the difficulties met with in the operation.

Dr. ENGER asked if the bowels were at any time twisted, or if their refrigeration by long exposure had had anything to do with the gangrene.

Dr. TILLEY said that the accident of leaving a foreign body in the abdomen happened oftener in this country than in Europe, because we had different assistants at different operations, whereas European operators always had the same assistants. The sponges should certainly be counted, or pieces of tape be attached to them. Regarding the confinement of the bowels for eleven days after ovariectomy, he did not think it judicious.

Dr. J. J. M. ANGEAR remarked upon the lessons that were to be learned from cases in which mistakes were made, and on the President's conscientiousness in reporting the case of death from a sponge having been left in the abdomen.

Dr. LISTON H. MONTGOMERY and Dr. PARKES dissented from the statement that foreign bodies were oftener left in the abdomen in this country than elsewhere.

CLINICAL SOCIETY OF THE

NEW YORK POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

Meeting of December 6, 1884.

Dr. THOMAS E. SATTERTHWAITE in the chair.

[From notes furnished by the Executive Committee.]

Discussion on Erysipelas.—Dr. EDWARD L. PARTIDGE opened the appointed discussion. Erysipelas, he said, like the exanthemata, was infectious and epidemic; it had a period of incubation, prodromes, and a definite course, but, on the other hand, it was less contagious than any of the exanthemata, and recurred with greater frequency, in these points resembling diphtheria and septicæmia. It was not interchangeable with the exanthemata or with diphtheria, but might possibly be with septicæmia and puerperal fever, and perhaps with typhus. In 1838 erysipelas and typhus existed together in an English hospital, and apparently were related in that instance. The relation with puerperal fever might perhaps be shown by the not uncommon case of the puerperal woman who died of septicæmia soon after childbirth, while the child died of a distinctly phlegmonous erysipelas. It was probably never of neurotic origin, nor was it necessarily preceded by traumatism, there being undoubtedly an idiopathic form in which the poison gained access in all probability through the respiratory tract. Of this latter view, however, we had no absolute proof, and the view which insisted upon the necessity of an abrasion was therefore entitled to respect. The disease was probably spread through the lymphatics, and it had been shown by Billroth that it was possible for it to be thus conveyed to the pleura or meninges, and inflammation of those tissues might be a complicating factor in the disease. A predisposing cause might probably be found in a sluggish condition of the wounded parts, as shown by flabby,

grayish granulations and scanty secretion, as well as in constitutional disease which impaired the venous return, as in disease of the liver, kidney, or heart. The mortality of erysipelas was greater in winter than in summer, being increased by a contaminated atmosphere; greater in the very young or very old than in the middle-aged; greater if the disease arose in the vicinity of wounds; and especially greater if there was any co-existing drain on the system from the heart or kidneys.

The best treatment was probably to rely upon general support and stimulation and to treat constitutional symptoms as they arose. A saline cathartic might be employed, with local depletion of the blood-vessels, to relieve the tension when it was great, and quinine when the temperature ran high. It was very doubtful whether specific treatment, or so-called abortive measures, were of any avail to limit the disease.

Dr. D. B. Sr. JOHN ROOSA was inclined to think, possibly from his surgical education, that erysipelas was always traumatic in its origin. In the one case, where he had not been able to find the lesion, he supposed that it existed so far back on the mucous membrane of the nose as to be out of sight. He did not believe that erysipelas could be generated on a sound skin or mucous membrane. He believed that every eczematous spot and every lesion of the mucous membrane in persons in hospital life, or in delicate persons anywhere, should be healed if possible. He considered the poor ventilation common in houses and hospitals during the winter months as one of the causes of the prevalence of the disease during that season, rather than the low temperature of the air. In his experience, cold did not produce the disease, but he thought the traumatism of a high wind blowing upon the face a very efficient cause. He considered the antipyretic use of quinine as useless and dangerous; the dilatation that preceded the contraction of the blood-vessels by quinine did much harm, the contraction preventing elimination, and when the temperature fell under its use no proper inference could be drawn, because at the best the temperature of erysipelas was capricious. He recalled a case in which the temperature fell from 104° F. to below normal under no other drug than tincture of chloride of iron. He would use no medicine except a purgative, when necessary, but would rely upon good air, good food, stimulation, and attention to the comfort of the patient. Locally he would use the lead-and-opium wash, which he considered the most agreeable, while the most disagreeable that he had found was the English application of white paint.

Dr. W. O. MOORE said that erysipelas was rarely a cause of eye trouble, or if it was the connection was not made out, as a rule, although we met with two forms of intra-ocular disease directly traceable to the poison of erysipelas, especially that of the face. The first was a thrombosis of the retinal vessels, due to a direct propagation of the inflammation along the walls of the vessels, causing thus, finally, an obliteration of their caliber, or in part to compression of the central retinal artery by the products of inflammation around the optic nerve and the orbit. It was rare that one had the opportunity of seeing these cases during the acute erysipelatous period. Since Dr. Knapp's paper was read, in the early part of this year, he had anxiously looked for such a case, and at last, on the 6th of August, he had seen one with the following history:

H. C., a male, aged thirty-nine, had received a slight cut, while being shaved, on the right side of the face near the ear. This soon became affected with the ordinary form of acute erysipelas, in three days spreading over the entire face, though most marked upon the right side. The eyelids were moderately swollen, but no protrusion of the eye was noticed. The erysipelas did not yield promptly; ten days after it began, on opening his eyelids, the patient noticed that his vision was impaired, although to outward appearances the eye was normal. On the fourteenth day Dr. Moore saw him, and, on ophthalmoscopic examination,

found much the same appearances in the fundus as had been seen in Coggin's and Knapp's cases, viz.: *Right eye*.—The media were clear, and the optic disc was clear in outline, but its substance was milky, as was also the retina near the nerve. The vessels were distorted and tortuous, and there was one small hemorrhage into the retina toward the periphery of the fundus. The arteries were smaller than normal, and carried less blood. Vision was $\frac{1}{20}$. One week later the eyelids were well open, the eye was clear and bright, the pupil moderately dilated, vision the same as before, the optic nerve whiter, the retina less milky, the vessels were smaller, looking as if no blood entered them, and the effused blood was undergoing absorption, one of the vessels looking like a white cord. In two months the patient was totally blind in the right eye, the other remaining in good condition. The only change in the appearance of the fundus was in the optic nerve, which was white and atrophic, with only a few vessels containing any blood.

The second picture we saw was that of the last stage of the disease, where the patient came, months after the erysipelas, with the ordinary picture of white atrophy of the optic nerve. In looking over records of cases of atrophy where a probable cause was given, he found, out of two hundred cases, only one upon which erysipelas was supposed to have a bearing. This percentage was, he thought, too high.

Dr. David Coggin, of Salem, Mass., in the "Trans. of the American Ophthalmological Society" for 1879, had reported a case of ischemia of the retinal vessels of both eyes after facial erysipelas.

The patient, who was sixty-two years old, had facial erysipelas of both sides, with some sloughing of the lids. There was chemosis. Five weeks after the commencement of the attack the lids were well open, the pupils dilated, the media clear, the right retinal vessels empty, and the left vessels also bloodless except for one vessel going upward. No difference could be made out between veins and arteries; the discs were of a grayish white, with no capillary vessels present in either eye. There was no cardiac or rheumatic history. Dr. Coggin's idea was that the erysipelatous inflammation was propagated under the capsule to the optic nerve, where it exercised enough pressure to retard the circulation in the retinal vessels, and thus caused thrombosis, or that thrombosis was due to extension of the inflammation to the vessels themselves. The patient never recovered his vision.

Dr. A. Carl, in the "Monatsbl. für Augenheilkunde," April, 1884, had reported a case of blindness from erysipelas. Erysipelas began at the tip of the nose, and extended over the face. Fifteen days from the beginning of the disease the right eye became blind, with protrusion and immobility of the globe. Dr. Carl saw the patient seven weeks after the blindness came on, and found the media clear, $V = 0$, the optic-nerve outlines clear, the disc milky and opaque, and the retinal vessels reduced in number, partially filled with blood, and partly reduced to white cords. Four months after blindness appeared, complete atrophy of the optic nerve was noticed, and some of the arteries had entirely disappeared. The left eye was normal.

Dr. H. Knapp, in a paper read before the Medical Society of the County of New York, March 24, 1884, said: 1. Blindness was produced by compression of the central retinal vessel and thrombosis of the retinal veins. 2. No neuro-retinitis was seen with the ophthalmoscope, but the successive stages of a thrombosis. 3. The white segments in the veins and arteries were white thrombi, and not hypertrophy of the walls of the vessels.

Dr. SENECA D. POWELL considered that the progress of anti-septic surgery during the past few years had done much to limit the spread of erysipelas. He did not think that idiopathic erysipelas, or erysipelas without traumatism, was of uncommon occurrence, especially upon the face. It differed from the traumatic variety in not being contagious. He had seen erysipelas set in after amputation of the breast, beginning about the wound and creeping down the left arm, returning up the arm, passing around the neck, down the other arm, then back across the neck, and again down the left arm, where it ceased. He was in the habit, if the patient had a full, bounding pulse, of

giving liquor ammonii acetatis (1 to 4 drachms), spirit of nitrous ether (1 to 3 drachms), and tincture of aconite-root (1 to 3 drops), every two hours. He used iron only in the idiopathic variety, employing a tincture made from the black oxide of iron three parts, hydrochloric acid ten parts, and alcohol thirty parts, with no water, instead of the official tincture, which contained both nitric acid and water. When, in either variety, the patient began to show signs of debility, he always gave alcohol freely. Locally, he considered the lead-and-opium wash, applied hot and the compresses covered with oiled silk, the best application; or, if this did not relieve the inflammation, heat applied by means of the hot bran-bags.

Dr. C. A. VON RAMDOHR thought that erysipelas depended upon a peculiar coccus, which, if introduced into the circulation of a puerperal woman, might give rise to erysipelas, puerperal fever, or peritonitis, and, therefore, prophylaxis was a very important matter. As to the question of how long a physician should wait after seeing a case of septicæmia, pyæmia, or erysipelas before attending a confinement case, it could be answered by the remark: If the physician knew what disinfection was he might go at once; if not, he should give up attendance altogether. He made it a rule, whenever he had seen a case of erysipelas, to make a complete change of clothing, to take an entire bath, and particularly to disinfect his beard, hair, and hands.

After this process he had attended confinements without any unhappy result. He made it a rule, however, not to examine very frequently after making out the presentation and position. He had seen the progress of the erysipelatous blush apparently checked by the injection of a three-per-cent. solution of carbolic acid into the sound tissue near the margin. Sixteen injections were made, and, though very much reduced at the time, the patient recovered.

Dr. G. B. HORE said it was very fortunate that the mucous membrane of the nose and throat furnished so slight an attraction for the spread of this disease, as compared with the face and the scalp. There was often present an early laryngitis, giving rise to a small, irritable cough, but it was very rare to find, even in extreme erysipelatous inflammations of any of the contiguous parts, a laryngeal inflammation sufficiently grave to induce ulceration, or an edema that would interfere with the respirations. The integument of the nose might be enormously swollen without more than an ordinary accompanying rhinitis, unless the deeper structures became affected, in which case, naturally, the course and duration of the disease were more or less aggravated. Amygdalitis also occurred at times, but was generally self-limited, and abscesses were rare. Altogether, the line of demarcation between erysipelas of the cutaneous surfaces and that of the mucous membrane was distinct, and rendered the latter structure little liable to more than passing subacute inflammations.

Dr. W. M. LESZYNSKY said that during the past week he had had a case of facial erysipelas in which the compound tincture of benzoin had seemed to have a good effect, applied locally as a means of limiting the disease. He had also seen another case in which the injection of a two-per-cent. solution of carbolic acid in different spots about the line of demarcation had seemed to have a beneficial effect. He thought that, in many cases where the recovery from a supposed erysipelas was very rapid, the disease might have been in reality a dermatitis, and the high temperature of erysipelas should be present to establish a trustworthy diagnosis.

Dr. S. J. McURT had used equal parts of carbolic acid and glycerin applied to a zone about two inches in width around the periphery of the inflammation, but in six cases under observation she had not noticed that any particular advantage was

gained by the procedure. She used tincture of chloride of iron internally.

Dr. F. B. CARPENTER considered aconite abortive in the sthenic variety, and cited a case of erysipelas which had occurred three times. The first two attacks, under the local application of the lead-and-opium wash, and the use of tincture of chloride of iron internally, ran their course in ten days; the third, although it began just like the others, was treated with aconite, and the patient recovered in four days.

Dr. A. F. BUECHLER considered that the experiments demonstrating a special coccus for the disease had been conclusive. Not only would inoculation with the culture of the third generation produce the disease, but the transported culture from a distant neighborhood would produce it just as certainly, and in this case it had the peculiarities of the disease as it existed in its native place. The coccus was always found in the lymphatics, and extending not with the current of the lymph but against it. After inoculation the period of incubation was from fifteen to sixteen hours.

Dr. J. H. HAWLEY had noticed that, when erysipelas was present in the hospitals with which he was connected, it was present, as a rule, in the other hospitals and in other parts of the city. A more or less epidemic influence seemed to control its development. He used the lead-and-opium wash, hot, cold, or in poultices, whichever was most agreeable to the patient. When tension existed, he made early and free incisions. He had also used the injections of carbolic acid around the border of the blush, but it seemed impossible to decide what this procedure accomplished, for the course of the disease was so erratic. He thought that the Lister dressing was useful to prevent infection, and had used it with a good result in a case of compound, comminuted fracture of the scapula from a bullet wound, applying it all about the wounded side. Shortly after, the temperature rose to 103° , and an erysipelas developed in the arm of the wounded side, which ran its course without involving the wound under the dressing.

Dr. H. G. LITTLE had used iodoform and collodion (a drachm to the ounce) as an external application, with apparent success. In erysipelas of the scalp in children he had made use of the white lead, which undoubtedly reduced the irritation and scratching, while the spreading of the inflammation was checked.

Dr. C. L. STEVENS, in his practice in Turkey, had met with many cases of idiopathic erysipelas, asthenic in character and resembling typhoid fever, so common in Oriental cities, though having a more favorable prognosis and a shorter natural history. In these idiopathic cases he had learned to rely mainly on proper nourishment, free stimulation, and good nursing, using local applications as palliatives, but with no intention of cutting short the disease.

Dr. C. H. BROWN used Trousseau's mixture as a local application, and thought that when the part was freely painted with it it limited the disease and relieved the pain. He considered that it might be of neurotic origin occasionally. He had seen the vesication following a blister applied for pleurisy take on an erysipelatous inflammation, with rapid improvement of the pleuritic symptoms, and remarked that it had been proposed to inoculate with the erysipelas virus to promote the absorption of such effusions.

Dr. S. M. ROBERTS formerly used equal parts of carbolic acid and oil of turpentine, and had thought that it limited the disease, but he now obtained as good results without it. When hyperpyrexia became dangerous he used quinine if the stomach tolerated it.

Dr. JOHN H. NESBITT had used the nitrate-of-silver pencil at the border of the inflamed surface, and had painted the edges with tincture of iodine and with tincture of chloride of iron in

many cases, without any appreciable benefit in limiting the spread of the disease. In cases of idiopathic facial erysipelas occurring in dispensary practice no internal treatment whatever was used, but he depended entirely on local applications, selecting that which seems to be the most soothing. He preferred the lead-and-opium wash in most cases. Some time ago he had been in the habit of sewing all scalp wounds carefully with catgut, but had frequently found it necessary to cut the stitches within two days, to relieve the pain incident to the tension and erysipelatous inflammation. During the past year he had washed all these wounds with a solution of the bichloride of mercury and then applied iodoform, cotton, and a bandage; under this treatment there had been no inflammation, while in many cases the wound had united by first intention.

Dr. JUSTIN HEROLD said that, while serving as house physician and surgeon of St. Vincent's Hospital, he had had under observation a large number of cases, erysipelas being for a time epidemic in the wards. On the 4th of October, 1883, a man with incarcerated inguinal hernia was operated upon, and the next day facial erysipelas developed, which also spread to the wound. Under energetic treatment this patient recovered, but was the starting-point of all the other cases that rapidly followed. In a few days a number of patients with compound fractures (twenty-six) began to show signs of the disease. The character of the disease was low and diffuse, which made the treatment difficult. One or two died within two weeks, while one other lived five or six months and then died of exhaustion. All had been inmates of lodging-houses before their admission to the hospital, and they were ill-nourished, intemperate, and in bad general health. Several other cases presented themselves at the Out-patient Department about the same time, and they might have produced further infection, while several more were treated in the ambulance, thereby infecting the surgeon, who was obliged to do the dressing in all cases of minor surgery. Even one of the first patients in the new wing contracted the disease in a slight degree. The epidemic became so alarming that all surgical operations were suspended for a time. The speaker himself contracted a facial erysipelas. The epidemic was only controlled by a thorough disinfection of all the contaminated wards by means of sulphur fumes. Whenever the temperature of several patients rose to 103° or over, others, with simple lacerated and contused wounds, would have a rise of temperature and other constitutional symptoms of erysipelas, but no local signs. In none of these cases was the dressing antiseptic in a strict sense. The treatment was both constitutional and local, cachectic conditions were corrected, when present, and light nourishment was ordered in every case. Stimulants, when indicated, were allowed in quantities not exceeding 36 oz. in the twenty-four hours. For high temperature, quinine was used, and to overcome the irritability of the stomach the pharmacopoeial solution of morphine, two drachms every four hours. If vomiting occurred, a hot poultice of mustard was placed over the abdomen, affording instant relief in the majority of cases; if delirium occurred, as it did usually, it was treated with twenty grains of bromide of potassium, five grains of chloral every two hours, with marked relief. Constipation was treated by enemata, and diarrhoea checked by giving five grains of subnitrate of bismuth, a sixth of a grain of hydrochlorate of morphine, and six grains of prepared chalk every three hours. Tincture of chloride of iron was of invaluable service in simple facial erysipelas, but in the other forms it did more harm than good, invariably inducing disturbances of digestion. Locally, the lead-and-opium wash was not of so much service as the one-to-forty solution of carbolic acid, while a wash prepared freshly from the powdered opium did better than either, when applied hot. A solution of nitrate of silver in dis-

tilled water (half a drachm or a drachm to the ounce) stopped the spread of the disease in every case and was a very valuable remedy.

The CHAIRMAN said that during the Franco-Prussian war he had seen erysipelas originating simultaneously in different barracks. Dampness of the atmosphere with a sudden fall of temperature was a prominent cause of the disease. He had seen a case in which the inflammation extended from the face to the mouth, and the tongue became enormously swollen, while the pharynx was invaded and oedema of the glottis occurred. This condition was relieved by incision, but the patient ultimately died. In many cases of simple erysipelas he had used collodion, painting a band an inch or two wide about the limb at some distance above the line of inflammation. After the first coating had dried the operation was repeated three or four times, and the result was constriction of the integument, which appeared to compress the superficial lymphatics and so limit the disease. For the phlegmonous form he had used olive-oil, rubbing it in well every day. In a case where both legs were affected he used the simple oil on one, and an eight-per-cent. carbolized oil on the other, with equally good results. Suppuration did not occur in either. He believed that there was a natural antagonism between erysipelas and pyæmia, so that an attack of the former prevented the latter. At some future time this natural antagonism might be used to practical advantage where pyæmia was feared. Inoculation with erysipelatous matter might be practiced to obviate the disease.

Dr. A. A. ALBURYAN said that, although idiopathic or non-traumatic erysipelas has been abrogated as a special disease by some prominent authorities, cases were met with almost daily in Eastern practice where no traumatism could be found. Local manifestations of erysipelas were often seen, in patients with chronic ulcers, confined to distant and otherwise healthy tissues. As the disease in all probability originated in vitiated air, and perhaps from some special micrococcus, which entered the circulation and produced symptoms of general disease with local manifestations, we had reason to think that the channels through which these microscopic organisms entered the system might be various. If they were able to penetrate through the cutis vera, we might naturally consider them capable of gaining ingress through a mucous membrane, which was practically only skin minus epidermis. Numerous clinical facts affirmed this. Another argument for the existence of a non-traumatic variety was found in the frequent absence of lymphangitis in the primary state of the disease, while in the traumatic form the lymphatic system was involved early. The non-traumatic form was not contagious, in his experience. In Oriental life, where the simplest hygienic laws were disregarded, there were no means of isolating these patients, and one often found a patient suffering with the disease surrounded by his family, who ate and slept in the same room, without taking the contagion. He did not think that one attack predisposed to another, and Fehleisen's inoculation experiments proved that there was an immunity for a period of a few weeks or months. Traumatic erysipelas had no particular period of incubation, but might occur at any time. He had had cases where it had set in in from ten to twelve hours after the operation. Local treatment by protectives was very promising. Collodion in many cases was objectionable, as it prevented cutaneous exhalation. Cold increased the discomfort and delayed resolution. Internally, quinine and iron in large and repeated doses, preceded by a saline purgative, was the usual treatment, both in hospital and in private practice, in Turkey. The mortality was insignificant. Death resulted from asthenia; hence cardiac depressants, if used at all, should be used with caution.

Dr. PHELPS had seen erysipelas cling to a bed, and not travel

about a ward. A patient having died of erysipelas, his bed and room were thoroughly cleansed and disinfected, but even then he had seen the next patient who occupied it attacked in one case. He was removed, and the next occupant also contracted the disease.

Depression of the Occipital Bone.—Histories of cases being in order, Dr. H. G. LYTLE presented that of a child, two months and six days old, with a marked depression of the occipital bone, with overlapping of the parietal. The child had slight convulsive movements of the hands and rolling of the eyes, with a disordered condition of the stomach and bowels. Dr. J. F. Hartigan had reported, in the "American Journal of the Medical Sciences" for January, 1884, forty-nine cases of trismus nascentium as being due to this cause. Dr. Lytle presented this case to show that the displacement of the occipital bone might occur without producing trismus.

Intussusception of the Jejunum.—A specimen was presented by Dr. WILLIAM H. PORTER. The patient, a lad seven years old, had been in the hospital for three weeks prior to his death. His symptoms were those of chronic hydrocephalus. He could not swallow well, and for the last few days was fed with milk through a stomach-tube. His bowels had only been moved by the use of enemata since the 1st of December. There were no symptoms of intussusception. He died from marasmus December 6th. At the autopsy, twelve hours after death, the body was found very thin, the head large, the heart normal, the left lung adherent, oedematous, and congested. There was no evidence of tubercles in either lung. The liver and spleen were normal. The kidneys were the seat of parenchymatous infiltration. At the lower third of the jejunum the intestine was invaginated, but without any evidence of peritoneal inflammation. Dr. Porter thought it of interest in connection with another case in which a similar condition was noted in an old man; in both the lesion was unusually high up, and no symptoms were present before death. The ependyma was distended, but no tubercles were found in the body.

Dr. ROBERTS remarked that at the Foundling Asylum this condition was found quite frequently at autopsies. From its frequency, and in the absence of inflammation and adhesion, he was of the opinion that it was developed just before death or during the death struggle. The intussusception in this case, however, was uncommonly high up in the intestine.

NEW YORK OBSTETRICAL SOCIETY.

Meeting of June 3, 1884.

Dr. HENRY F. WALKER in the chair.

Retained Menses from Imperforate Hymen.—Dr. ROBERT WATTS related the case of a girl, seventeen years old, who had never had any menstrual discharge, but had suffered with symptoms of retention for only two months—abdominal pain and swelling, with a small separate swelling in the right iliac fossa, and distension of the perineum. About a quart of dark liquid blood was drawn off with a large trocar, thorough evacuation being secured by making pressure on the abdomen. The liquid was not offensive. The puncture was then stretched wide open, and warm carbolized water was injected freely. The uterus contracted well, and the swelling in the right iliac region was found to be connected with the ovary. Iodoform gauze was inserted in the vagina, and carbolized injections were afterward used. No unfavorable symptoms occurred, but there was now a tendency to agglutination of the walls of the vagina, in consequence, perhaps, of the over-distension to which the canal had been subjected.

The CHAIRMAN referred to a case that he had seen, in a girl

fifteen years old, in which a free opening was made, and no bad symptoms took place, although no injections were used.

Dr. FRANK P. FOSTER referred to the reasons that had been given by Dr. Emmet, at a previous meeting of the society, why the plan of rapid and complete evacuation should tend to prevent rather than to favor bad results.

The CHAIRMAN and Dr. WATTS thought rapid evacuation was the proper treatment.

Dr. EDWARD L. PARTRIDGE mentioned the supposed danger of the entrance of air, from defective uterine contraction.

Dr. WATTS thought the use of antiseptic injections would overcome that danger, and in this opinion Dr. ALEXANDER S. CLARKE coincided.

Dr. EDWARD H. PEASLEE had heard his father speak of an instance of rupture of the Fallopian tube from too rapid removal of the liquid.

Dr. HENRY D. NICOLL referred to a case that occurred at Bellevue Hospital, in the service of Dr. Isaac E. Taylor, which was complicated with atresia of the lower two inches of the vagina. An operation was performed, ergot was given, and "following down" of the uterus was employed, as after labor.

Mercurial Poisoning from Intra-uterine Injections.—Dr. PARTRIDGE related the history of a case of labor that had occurred at the Nursery and Child's Hospital in which vaginal injections of bichloride of mercury, 1 to 2,000, were used, and the patient did well for three days. On the third day she had a chill, and the house surgeon gave an intra-uterine injection of the same solution. The next day there was another chill, and the injection was repeated. This was followed by bloody passages from the bowels, and death took place. Intense colitis was found post mortem. Dr. Partridge referred to reports of three other cases of supposed mercurial poisoning from the same cause. The patient whose case he had related died within sixty hours from the administration of the first intra-uterine douche.

Dr. COLIN MACKENZIE had known severe uterine colic result from a vaginal bichloride injection.

Cystitis from a Mercurial Injection.—Dr. PARTRIDGE also related a case in which, by mistake, a nurse threw a bichloride injection into the bladder instead of into the vagina, and severe cystitis was set up—quite as much, perhaps, from mechanical violence as from any special action of the bichloride.

Dr. FOSTER referred to a case that had been reported by Dr. Thomas, in which it was a carbolic-acid solution that had been used.

Spontaneous Disappearance of Sterility.—The CHAIRMAN mentioned a case that had come under his observation in which a lady became pregnant for the first time after seventeen years of wedded life. One year after her marriage the os externum was incised, but there had been no subsequent treatment directed to the removal of sterility.

HENRY J. GARRIGUES, M. D.,
B. F. DAWSON, M. D.,
FRANK P. FOSTER, M. D., *ex officio*,
Committee on Publication.

Miscellany.

THERAPEUTICAL NOTES.

The Use of Cold in Midwifery.—Dr. Grognot ("Bull. gén. de thérap.") speaks highly of the emmenagogue properties of external applications of cold. Being convinced that the uterine contractions induced by ergot, faradization, and massage were transitory and ineffi-

cient, he was led to try the effect of cold, which he regards as superior to either of the other agents. He summarizes the advantages of cold as follows: 1. If cold is applied during labor, the contractions become stronger. 2. There is no danger either to the mother or to the child. 3. The agent is always at hand, and requires no instruments for its application. 4. Cold can be used in every stage of labor, for the expulsion of the placenta as well as for that of the fetus.

"Mixed" Anæsthesia.—The practice of preceding the inhalation of chloroform or ether by a subcutaneous injection of morphine or of atropine is advocated by Columbel ("Lyon méd."), who states that the narcosis is more rapidly induced and more complete, that the unpleasant after-effects are avoided, and that the atropine diminishes the irritability of the cardiac ganglia, thus lessening the danger of paralysis of the heart.

The Disinfection of Tuberculous Sputa.—According to the "Centralblatt für klin. Med.," Schill and Fischer have made numerous experiments to determine the best means of sterilizing phthisical sputa, with the following results: 1. Steam sterilized dried sputa in thirty minutes, and liquid sputa in fifteen minutes. 2. A solution of bichloride of mercury, even of the strength of 1 to 500, had no effect. 3. Absolute alcohol was not invariably efficient. 4. It was necessary to use a five-per-cent. solution of carbolic acid before its sterilizing effects were observed.

The Cold-Water Coil.—It is somewhat amusing to read, in the "Wiener med. Blätter," that Dr. Mader, of Vienna, has modified Leiter's metallic coil by substituting rubber tubing for that of lead. The advantages of this new (?) device are set forth at length, the writer being evidently quite ignorant of the fact that the rubber coil has been in use for several years in this city.

Küchenmeister's Treatment of Diphtheria.—The "Allgemeine med. Central-Zeitung" gives the following formula, which has been used by Küchenmeister for several years:

Nitrate of sodium,	
Carbonate of sodium, each.....	30 grains;
Syrup.....	5 drachms;
Water.....	3 ounces.

The dose is not mentioned. Küchenmeister believes that the salts of sodium act directly upon the albuminates of the blood. Several times a day he applies locally a solution of corrosive sublimate (1 to 2,000), and uses the same solution (to which four times as much lime-water has been added) for a gargle, thus turning to account both the dissolving action of the lime-water upon the diphtheritic membrane and the parasiticide properties of the mercurial.

Agaricin.—Piering ("Prager med. Wochenschr.") gives the results of a series of experiments with this drug. It was administered principally to patients with cardiac and pulmonary affections, in doses ranging between one twelfth and one half of a grain. A slight increase in the frequency of the pulse was noted after its use, but no change in the temperature. Sleep was frequently induced. Unpleasant after-effects were never seen, as they sometimes are after the use of atropine. The following is a brief summary of the writer's conclusions: 1. Agaricin is a safe and valuable remedy for the night-sweats of phthisis. 2. It has no influence on normal perspiration. 3. In doses of one sixth of a grain, frequently repeated, it causes a rapid diminution of the sweating, this effect beginning within five hours after its administration is begun. 4. No bad results follow its use.

The Treatment of Polyuria.—Lunin ("Jahr. f. Kinderheilk.") reports a confirmed case of polyuria in which the daily amount of urine was reduced within a week from eight to five litres by seven-grain doses of salicylate of sodium. Valerian was then given (an infusion of the root, 1 part to 20 of water), with the result of further reducing the amount to two litres and a half. Within three weeks the amount of urine fell almost to the normal, and there was a decided improvement in the general condition of the patient.

Turpentine Applications in Rheumatism.—Constantin Paul ("Union méd.") speaks highly of the plan of enveloping the affected joints with thin flannel compresses (not thicker than "a sheet of paper") dipped in oil of turpentine. They should be covered with oiled silk or rubber cloth, and should not be kept on more than an hour, for fear of producing vesication.

Resorcin in the Treatment of Poisoned Wounds.—Anderc ("Monatsh. f. prakt. Dermat.") reports a series of cases in which dissection wounds accompanied by inflammation of the lymphatics, and in some cases by constitutional disturbance, were treated with applications of an ointment containing equal parts of resorcin and vaseline. The urine showed the greenish color indicative of the absorption of the drug, and in every case the pain and inflammation were relieved within a few hours.

Arbutin.—Paschke ("Wiener med. Presse") has tried this glucoside, obtained from the leaves of the *Arcostaphylos uva ursi*, in sixteen cases of blennorrhœa and cystitis, and, so far from its having any diuretic action, there was no change in either the amount or the reaction of the urine.

Phosphorus in the Treatment of Craniotabes.—Betz ("Memorabilien") reports good results from external applications of a mixture of one sixth of a grain of phosphorus and an ounce of olive-oil, unguions being made with it every night and morning.

The Treatment of Rickets.—The ("Centralbl. f. d. ges. Therapie" gives the following formula, suggested by Lesser:

Tincture of rhubarb.	5 drachms;
Acetate of potassium.	2 "
Wine of antimony.	75 minims.

Dose, five to ten drops three times a day, gradually increased to thirty drops.

An Injection for Urethritis.—Cambillard ("Union méd.") suggests the following formula:

Bromide of potassium.	6 parts.
Laudanum.	2 "
Glycerin.	10 "
Distilled water.	150 "

For acute urethritis, attended with painful erections, use four injections daily, the last one to be taken just before going to bed. The liquid should be retained in the urethra for a few minutes, in order to obtain its sedative effect.

Pills for Uterine Hæmorrhage.—Gallard, according to the "Jour. de méd. et de chir. prat.," uses pills made as follows:

Ergotin,	
Subcarbonate of iron, each.	180 grains;
Sulphate of quinine.	36 "
Powdered digitalis.	18 "

Divide into one hundred pills. Four to be taken daily.

Tetanus following Hypodermic Injections.—In the "Gazzetta degli Ospitali" Dr. Bartolazzi reports that, among a thousand cases of malarial disease that he has treated with hypodermic injections of quinine, he has twice met with fatal tetanus. In one instance only two injections had been given, each of six grains of sulphate of quinine and a sixth of a grain of morphia. In the other case but a single injection had been given. He ascribes the occurrence to the neurotic character of the patients, and possibly also to certain atmospheric influences.

Formic Acid as a Germicide.—The conditions of animal life vary immensely; the introduction of a single influence, not apparently of a powerful nature, may determine the death of some organisms. M. Schnetzer, a few weeks ago, communicated some observations to the Académie des Sciences which serve to illustrate the above general principle. He has found that *Bacterium subtilis*, one of the most difficult micro-parasites to kill, dies when in the presence of formic acid. Even when this bacterium has resisted the action of boiling water for one hour, it may be instantaneously killed by formic acid; a drop of water containing a thousandth part of formic acid to a drop of water teeming with thousands of the bacteria, is sufficient to effect the purpose. The swarming fluid so treated may be introduced into the digestive tract with impunity. The author recommends the trial of formic acid on the cholera bacillus, and it may be suggested that its action on *Bacillus anthracis* is equally deserving of experiment. If formic acid should be found to be capable of destroying the dried virus of charbon, provided this chemical agent does not injure imported wool—and in such a diluted

state injury seems impossible—the suggestion that all imported wool be washed in a weak solution of formic acid might be of value in preventing the occurrence of so fatal a disease as malignant pustule and its allies.—*Lancet*.

Accidental Puncture of the Gravid Uterus during Ovariectomy.—In the "Australian Medical Gazette" Mr. George Fortescue reports a successful case of Porro's operation, the details of which are, briefly, as follows: The patient was a young woman (unmarried) who had remarked for several months an enlargement of the lower part of the abdomen. When she was examined, a colloid cyst was diagnosed, occupying the site of the right ovary. It was tapped, and a second, smaller tumor was found on the left side. The patient had missed one menstrual period. Four months afterward the operation was performed, there being no signs of pregnancy save continued suppression of the menses. On opening the abdomen, a large cyst was first punctured and emptied, when a smaller tumor appeared at the wound and was likewise tapped, and a watery fluid was withdrawn. This was then found to be the gravid uterus. It was removed at once, and the patient made a speedy recovery.

A Series of Ovariectomies.—Mr. Meredith, of London, publishes fifty cases of ovariectomy in the "British Medical Journal," the work of three years. Forty-six of the patients recovered, making a mortality of only eight per cent. The operations were all performed under spray, and with due antiseptic precautions, to which course the writer attributes the fact that he was able to dispense with a drainage-tube in all but three cases. Mr. Meredith urges as an argument against hyperpyrexia being due to the absorption of carbolic acid the fact that in forty-two of his cases the temperature did not exceed 102° F. Nine other cases of laparotomy for various causes are appended to the report, of which one was fatal. These statistics are valuable, as the writer is well known to be Mr. Knowsley Thornton's assistant and an able exponent of his methods.

The Results of Removal of the Larynx.—Zesas ("Arch. f. klin. Chir.") sums up the results of this operation as follows:

Diseases.	Cases.	Recoveries.	Deaths.
Sarcoma.	5	2	3
Carcinoma.	60	15	42
Syphilitic Stenosis.	1	..	1
Perichondritis.	1	..	1
Tuberculosis.	1	..	1
Polypus.	1	1	..
Papilloma.	1	1	..
Total.	70	19	48

He infers from these statistics that we can positively state that the removal of the larynx for malignant disease is not a legitimate operation. We must remember that primary cancer of the larynx remains localized for a long time, and rarely gives rise to general infection. Recurrence is more likely in patients of an advanced age.

The Microbe of Syphilis.—M. Bricon contributes an interesting article to the "Progrès médical" upon the "syphilicoccus." After reviewing the literature of the subject, he draws the following conclusions: 1. Syphilis is a parasitic disease. 2. The microbe of syphilis is a micrococcus, because, if we except some few authors who have described it as a bacterium, or bacillus, most writers refer to a micrococcus of a character still undefined. 3. Inoculations made with the products of syphilis have been unsuccessful, or at least doubtful, M. Martineau's unique case (that of an ape) being perhaps an exception.

Surgical Instruments of the Second or Third Century.—The "Union médicale" gives an interesting account of some old instruments discovered by M. Toulouze while making excavations on the site of an ancient Roman way, on the *rue Clovis*, in Paris. The first one had a shaft 14 cm. long, terminating in an olive-shaped knob at one end, and being curved like a crotchet at the other. It was probably used as a probe in cases of foreign bodies at the bottom of a deep wound. The second was a small bronze ear-scoop. The third was an epilation forceps. M. Toulouze assigns these articles to the age of Galen.

Original Communications.

THE RELATIONS BETWEEN TUBERCULOUS JOINT DISEASE AND GENERAL TUBERCULOSIS.*

BY FREDERIC S. DENNIS, M. D.

MR. PRESIDENT AND GENTLEMEN: The past few years have marked important changes in our views regarding the traumatic origin of joint disease. Recently pathologists have proved that joint disease in the great majority of cases is primarily due to tuberculosis, and that traumatism is either only a secondary factor in the causation, or, if it is ever the primary cause, the cases are very limited in number. The experiments and observations which have been made upon lower animals in pathological laboratories appear to accord with what surgeons have found clinically to be the case in studying joint disease in man, and all these experiments in which joint disease is produced artificially in lower animals have been found to have a counterpart in the human body. This radical change of opinion in regard to the etiology of joint disease has not yet been accepted by some surgeons, and the occasion of the meeting of the New York State Medical Association is an appropriate one in which to discuss such an important topic in surgical pathology. The object of the present paper is to present some microscopical and pathological specimens which show beyond peradventure the tuberculous origin of joint disease, and at the same time to avail myself of these specimens to discuss the relation between tuberculous joint disease and general tuberculosis. The time allotted to me does not permit of a discussion of the clinical history, diagnosis, prognosis, and treatment of tuberculous joint disease. A discussion of these topics, which are of paramount importance in connection with tuberculous joint disease, will be deferred for the present, and will form in the future a subject for another paper. Before entering upon a discussion of the relation between tuberculous joint disease and general tuberculosis it is well to attach some definite and precise meaning to these terms. This preliminary step seems necessary, not only on account of the confusion which has been caused by the recent introduction of these terms into surgery and the indiscriminate use of these words by surgical writers, but also because a clear understanding of the nomenclature is indispensable at the outset in order to intelligently discuss the subject.

By a tuberculous joint is meant a joint in the different tissues of which the *Bacilli tuberculosis* of Koch are present, though it does not always follow that they can be found; and by general tuberculosis is meant acute miliary tuberculosis. The *Bacilli tuberculosis*, which are the infective agents, are developed in a central focus, and the focus in the majority of the cases consists of a broken-down, caseous lymphatic gland, and from this focus dissemination of bacilli proceed and cause acute miliary tuberculosis. Another term

for the caseous lymphatic gland is scrofula, and hence it is apparent that scrofula acts by furnishing a suitable soil in which the infective agents develop. It does not come within the province of this paper to discuss the relation of scrofula to tuberculosis; but it will suffice to state that pathological experiments and clinical history prove without doubt that an intimate relation exists between these two affections. The best proof of this statement lies in the fact that the appearance of scrofula is usually associated with the presence of tuberculosis, and that when one condition is present the other condition is almost invariably found. Tuberculous joint disease, however, can develop primarily without the presence of scrofula, or the joint disease can be secondary, as when metastasis occurs from an organ in which infective agents are present. Thus, as metastasis may occur in the lungs from a caseous degeneration of the bronchial glands, so a tuberculous peritonitis may arise from caseous retro-peritoneal glands, or, as in a case recently reported in "La France médicale," a tuberculous osteitis was developed by metastasis from a tuberculous pleurisy which antedated the osteitis a year.

A knee joint may become primarily attacked by tuberculosis without any other focus; this condition has been seen in autopsies, although it is rare in proportion to the number of cases in which the joint disease is the result of a metastasis. It has been shown in quite a number of cases that a primary source of tuberculous osteitis, in the vicinity of the knee, for example, has been a focus situated in the cancellated tissue of the lower epiphysis of the femur, and that the caseous products of the central focus have discharged themselves in a direction away from the knee joint, and that the patient has thus narrowly but fortunately escaped local joint infection. This important clinical fact teaches a practical lesson of great value—that surgical interference can avert and ward off a general tuberculosis if the caseous abscess is trephined, thoroughly gouged out, and carefully scraped with a Volkmann's spoon. Iodoform packed into the abscess cavity and sulcus destroys any of the remaining infective agents, and general dissemination is thus prevented. My own clinical experience has illustrated this in tuberculous osteitis in several cases where this method has been employed. In a recent contribution Professor Volkmann made an analysis of two hundred and fifty cases of excision of the hip for joint disease, and could find in the entire number only five or six cases which were not tuberculous. Koenig relates a case where a resection of the knee was performed for tuberculous joint disease. The wound was aseptic, and, two weeks after the resection, symptoms of acute miliary tuberculosis were well pronounced. The patient died, and the autopsy revealed the presence of miliary tubercles in nearly all the organs of the body. The same author reports another case where, three weeks after resection of the hip, symptoms of general infection supervened, such as headache, projectile vomiting, facial paralysis, and coma. The patient died, and the autopsy showed the cause of death to be acute miliary tuberculosis. In all the organs tubercles were found, and the starting-point or focus was in a broken-down lymphatic, caseous abscess of the

* Read before the New York State Medical Association, November 19, 1884.

neck. This same writer adds still another case illustrating the general principle, but affording at the same time an example of local primary infection in a joint to which reference has already been made. This patient died two weeks after a resection of the hip joint, and the post-mortem examination revealed the cause of death to be acute miliary tuberculosis, and that the starting-point in this case was an abscess in the head of the femur. Recently a surgeon has reported a case of acute miliary tuberculosis developed by dissemination of tubercles from a strumous abscess of the mastoid cells. This case is in marked contrast to two which were sent to me, and in which cases, after trephining, gouging, and scraping the mastoid cells, the patients both recovered and enjoyed excellent health. While these last two cases which have come under my own observation are wholly inadequate to establish any precedent on account of the limited number, they nevertheless serve as links of evidence in the chain of argument which will be presented in the conclusions of this paper. Acute miliary tuberculosis has followed in a limited number of resections, which suggests at once to our minds that any operation which has for its object the destruction of a central focus must be early, thorough, and complete.

Professor Albrecht, of Zurich, has recently published an article in the "*Deutsche Zeitschrift für Chirurgie*" in which he tabulates three hundred and twenty-five cases of joint disease in reference to the aetiology of the affection. He has pointed out in this contribution that the joint disease in one third of the entire number was associated with scrofula, and that in only one sixth of the number could the joint disease be traced to traumatism. He also demonstrated that the mortality in joint disease was twenty-two per cent. greater when scrofula was associated with the joint affection than when the disease could be traced to traumatism.

These clinical facts clearly prove that there must be a causative relation between tuberculous joint disease and general tuberculosis; but exactly what this relation is, and how it is to be scientifically defined, are questions most difficult to answer in the present chaotic state of our knowledge of tuberculosis. I shall endeavor, however, to throw as much light upon the subject as clinical observation and experience permit, and at least show that a relation does exist between these affections.

The distinction between acute miliary tuberculosis and local tuberculosis has been compared by pathologists to the difference between pyæmia and ordinary suppuration. Pyæmia, which is a form of suppuration always associated with metastatic abscesses, is altogether different from common suppuration. Hence it is evident that acute miliary tuberculosis is a special variety of the many diseases termed tuberculous, just as pyæmia is a special variety of common suppuration. While this comparison serves for the purpose of clearly defining the difference between pyæmia and common suppuration on the one hand, with acute miliary tuberculosis and local tuberculosis on the other hand, the comparison has been further employed by pathologists to explain the similarity in the mode of origin and method of dissemination between acute miliary tuberculosis and pyæmia. In pyæmia there is an infective focus from which

infective emboli start, and these develop metastatic abscesses. These infective emboli, as Heuter has shown, contain micrococci, and it is by the presence of these microorganisms that the small miliary and the large metastatic abscesses are produced in distant organs which are connected by vessels proceeding directly from the seat of infection. If the infective embolus is detached from an infective thrombus and swept through the blood-channels belonging to the portal system—as, for example, after the operation for the removal of hæmorrhoids—the metastatic abscess is found in the liver; if to the systemic system—as, for example, after the operation of trephining in compound fracture of the skull—the metastatic abscesses are found in the lungs—though exceptionally these abscesses may occur in the liver, even in an injury to the head, when the emboli are small enough to pass through the pulmonary capillaries, or when they pass by anastomosing vessels direct to the liver. In acute miliary tuberculosis there is also an infective focus, as in pyæmia, and this focus is a broken-down caseous lymphatic abscess, and from this scrofulous focus acute miliary tuberculosis develops and is disseminated throughout the body; but, instead of developing metastatic abscesses, as in pyæmia, there is found a collection, or, in German phraseology, a "herd" of miliary tubercles in the different organs and tissues of the body. As a point of contrast, it is worthy of comment to state that the blood-vessels are the channels of dissemination in pyæmia, and the lymph-vessels principally in tuberculosis. While, then, the dissemination of infective agents is similar in pyæmia and in acute miliary tuberculosis, the nature and characteristics of these infective agents differ widely.

This clinical fact has been proved by experiments upon the lower animals, for pyæmia has been developed in the lower animals by inoculation of putrid material, and acute miliary tuberculosis has been produced by inoculation of the *Bacilli tuberculosis*.

Multiple foci, which are situated in broken-down, cheesy, lymphatic glands, in which bacilli develop and multiply, have been the source from which dissemination of acute miliary tuberculosis has proceeded.

Professor Gross, during the course of some valuable remarks upon the subject of tuberculous joint disease, called the attention of the association to the fact that tuberculous joint disease and general tuberculosis might be compared to the dissemination of carcinoma, which may be local at the outset and general in the later stages of the disease. The analogy, I think, may be carried still further to include sarcoma, in which the infection is local at first and general as the disease progresses. In the case of carcinoma, the disease spreads by means of the lymphatic channels—a method of dissemination which corresponds to tuberculosis—while in sarcoma the disease spreads by means of the blood-vessels. I am inclined to the opinion, after much hard study, close observation, and clinical experience, that all malignant tumors have at the outset a local origin, and that general infection in the great majority of cases can be prevented if surgical interference is made early in the history of the disease. This view is at variance with that of many surgeons, and few authors will indorse the statement. Whatever theory

may be adopted in regard to the ætiology of tumors, whether Cohnheim's, or Virchow's, or other pathologists', they may all be partially, if not entirely, reconciled to this view by clinical experience. Tuberculous joint disease behaves like carcinoma and sarcoma in the dissemination, and the analogy in the clinical history still is observed. In support of the view of the local origin of these diseases, I might cite at least a dozen cases upon which I have operated, and of which I have carefully preserved the notes, which indicate that, no matter what variety of malignant disease is found, early interference may prevent general infection and death. These tumors were all carefully examined by Professor Welch, who pronounced them malignant. I have seen the cases from time to time, and in all of them over two years have elapsed, and in some nearly ten years; at least a sufficient time has passed to make one confident in the belief that return will not take place. I have in my case-book notes of twenty cases which I have examined, and have found death to have occurred by metastasis after removal of a malignant growth; but in all of these cases I am convinced that the operations were deferred until too late, when general infection has already been established, and that, had early operation been resorted to, the cases might have terminated differently. I have still other cases which are under observation, a sufficient time not having elapsed for purposes of establishing any principle.

In the tuberculous joint disease my experience accords with what has already been said in regard to malignant tumors—that early operation will prevent dissemination, and that the disease at the outset is purely a local infection. The number of cases operated upon justifies the statement that early and thorough operation, or, what is better, treatment which is directed to the management of the local infection, is attended with excellent results.

Before referring to the specimens which are to be examined, it may be well to mention a few salient points in connection with the history of the patient from whom the specimens were taken, in order to better understand the relation of the joint disease to the general tuberculosis which followed.

G. V., aged twenty-two, single, by occupation a farmer, was sent to me by Dr. Knight on February 13, 1884. In the spring previous the patient sprained his wrist while plowing. For ten months before admittance to hospital he suffered from an inflammation of the wrist joint, which he attributed to traumatism. Upon examination of the wrist at this time, which was nearly a year subsequent to the accident, there was found fluctuation in the joint. The hand was useless, painful, and swollen. Two incisions were made, the pus was evacuated, and a drainage-tube introduced. The forearm and hand were placed upon an anterior splint. The joint was washed out daily with bichloride solution (1 to 2,000), and the patient temporarily improved. In a fortnight a new inflammation was set up, with cellulitis of the forearm. When this attack had subsided, in April, 1884, the patient was anesthetized, and a thorough exploration of the joint was made, with a view to resection or to amputation, according to the condition of the parts. Upon freely opening the joint by two lateral incisions, the carpal bones were found carious, also the heads of the metacarpal bones and the lower extremities of the radius and ulna. The joint was filled with pus and a gelatinous, pulpy mass. The conditions were so

unfavorable for a resection that amputation was performed by Teale's rectangular flap method. The patient recovered in a rapid and satisfactory manner. The wound healed by primary intention, with no constitutional disturbance. The joint and hand were examined by Professor Welch, who found *Bacilli tuberculosis* in the thickened, gelatinous mass. This at once established with accuracy, and beyond all doubt, the diagnosis of tuberculous joint disease, and forms the most important link in the chain of evidence to follow. Nearly three weeks after the operation, during which time the patient had been up and about, and was apparently in good health, he was seized with violent projectile vomiting, rise of bodily temperature, slight facial paralysis, and severe headache. The vomiting, headache, and delirium persisted, in spite of everything which was done to relieve him. The patient died after eight days; but shortly before death became comatose, and had rigidity of the post-cervical muscles, but no inequality in his pupils. The abdomen was retracted, the bowels were constipated, and the temperature just before death was as high as 103° F.

Professor Welch made the autopsy, which revealed abundant gray miliary tubercles at base of brain, especially in the fissura Sylvii and along the chiasm and tracts. The report of the autopsy further shows that there were tubercles upon the lower part of the convexity of the brain and also on the choroid plexus. The peritoneum, liver, spleen, lungs, pleura, and meninges were studded with gray miliary tubercles. The left kidney was found full of cysts, containing a thin, whitish, turbid fluid, holding cheesy floccules in suspension. The cyst-walls contained cheesy masses; the left ureter was three times its normal thickness; the cavity of the ureter was not much dilated, but contained dry, caseous material, which occluded the lumen of the duct.

The left seminal vesicle contained turbid white fluid. The left epididymis presented a few small caseous foci, and the corresponding testicle contained a few gray miliary tubercles. The left vas deferens was patent, but in some places contained cheesy material in its walls and lumen.

The right kidney was large and soft, and contained some small miliary tubercles, a few of which had cheesy centers. The right ureter was normal. The right seminal vesicle contained also turbid white fluid. The right epididymis was somewhat enlarged, firm, and nodulated, and contained a mass of friable, yellowish-white caseous material in nodules. The right testicle was filled with large, firm, gray, discrete miliary tubercles. The right vas deferens was filled along its whole course with caseous material, which was partly liquefied. There were many other points of interest in the autopsy, which was fully reported through the kindness of Professor Welch; but only those points have been given in detail which have a special reference to the subject under discussion. The prostate gland contained gray miliary tubercles and a few small caseous nodules.

The floor of the pars prostatica of the urethra presented many miliary tubercles, a few of which were cheesy. A few scattered, small, translucent tubercles could be seen in decreasing number along the urethra from behind forward. There was an indistinct, transverse cicatricial band at the junction of the membranous and prostatic portions of the urethra. This, then, is a case of primary genito-urinary tuberculosis; the disease began in the testicle, from this focus general tuberculosis was disseminated, and the relation of the wrist joint to the general tuberculosis is yet to be considered.

The most important questions which naturally suggest themselves in connection with this interesting and classical case are these:

First. Did the joint disease in which the *Bacillituber-*

culosis were found develop the acute miliary tuberculosis? *Second.* Did the scrofulous, cheesy abscess of the testicle afford a suitable soil in which were developed the bacilli which were the cause of the tuberculous joint disease? The solution of these difficult problems is not easy; but, judging from a study of many cases and from clinical experience, and from results obtained by inoculation of lower animals, the conclusions which the author arrives at are that both of these factors enter into the causation of acute miliary tuberculosis, and that in very exceptional cases either of these factors may act to develop acute miliary tuberculosis.

To present these questions again in a suitable form for discussion, without a special application to the case which has just been considered. They are these:

First. Does a joint become the seat of a scrofulous affection absolutely and *in toto* because the bacilli are there from the very outset, and, consequently, give to it the characteristic inflammation? or,

Second. Does a joint become inflamed as a result of traumatism, and then a simple traumatic synovitis or arthritis become converted into a tuberculous joint disease on account of the entrance of the *Bacilli tuberculosis* from a broken-down cheesy, scrofulous gland into an already inflamed joint.

And now, Mr. President and gentlemen, I am enabled to present to you for microscopical examination, through the kindness of Dr. McNamara, one of the assistants in the Carnegie Laboratory, the *Bacilli tuberculosis* which were found in this wrist joint after the amputation, but before any general symptoms of acute miliary tuberculosis were developed. I have also here before me on the table the post-mortem specimens which illustrate the pathological changes of the organs which were infiltrated with acute miliary tuberculosis. The consideration of the clinical history, the demonstration of the bacilli, and the presentation of the post-mortem specimens, form a most interesting and unique group, and the conclusions which I would draw from this case and from these specimens are these: *First*, that acute miliary tuberculosis is an infectious disease which is disseminated through the body from a central caseous focus, which focus in this particular case was situated in the testicle. That I am justified in forming this first conclusion, I have only to refer to the brilliant experiments of Burdon Sanderson, Klein, and others, who have inoculated lower animals with scrofulous matter obtained from a cheesy mass, and who have developed in lower animals a disease similar to acute miliary tuberculosis in man; and, moreover, that the same disease has been developed by inoculation with the pus from a cold abscess and from the granulations of a strumous joint. Further in support of this first conclusion may be cited Max Schüller's interesting experiments, where he caused lower animals to inhale tuberculous products, and developed in them general tuberculosis. The joints of these infected animals were then subjected to contusions, and the result was the development of a tuberculous joint disease. Still further in support of this first conclusion may be mentioned the startling clinical fact that some of these animals which were subjected to imprisonment with the infected animals suffered from joint disease

of a tuberculous character. It is a most noteworthy fact that, whenever rigid precautions were taken to guard against any possible infection, tuberculous joint disease did not supervene upon injury to the joints. These important clinical facts clearly demonstrate to us the infectious character of tuberculosis, and suggest to us the wisdom of recommending precautionary measures in the treatment of the disease from a medical point of view. These experiments upon lower animals place beyond all possible doubt the infectious character of tuberculosis and its intimate relations with acute miliary tuberculosis.

The second conclusion is that the removal of scrofulous, cheesy, broken-down glands, with a central caseation, which are frequently the starting-points of general tuberculosis, is a means of eliminating one of the chief sources of general tuberculosis and tuberculous joint disease. This second conclusion, I am aware, will not be accepted by some surgeons in this audience; but still the evidence is beyond doubt in the minds of those who have given the subject thoughtful study. Monsieur Rendu, whose valuable contributions upon this subject may be found in "L'Union médicale," 1881, has accepted the view that scrofula and tubercle bear the same relation to each other as soil to seed, and that in scrofulous soil tubercles rapidly grow and multiply, until from this focus acute miliary tuberculosis is disseminated. In support of this second conclusion I would state that, in cases of death from general tuberculosis and tuberculous joint disease, the post-mortem examinations show that caseous masses are absent in only twenty per cent. of the cases. In all probability these caseous masses are absent in less than twenty per cent. of the cases, for these masses may have been either overlooked, or changes may have occurred to obliterate the traces of an old abscess. There must be also subtracted from the original twenty per cent. those cases, though few in number, where the joint affection was primarily a local disease. Thus it is evident that, when these deductions are made from the twenty per cent., there is but a small per cent. left of the cases of tuberculous joint disease in which strumous and scrofulous glands are not actually proved to be the starting-points of acute miliary tuberculosis.

In the case the specimens of which are before me, the starting-point was, in all probability, in the caseous, scrofulous, lymphatic abscess of the testicle. That these foci finally are the starting points can be demonstrated almost at any autopsy, for they are easily found, except in the very limited number of cases, amounting only to a small per cent. If, then, acute miliary tuberculosis can proceed from this condition of the gland, it is of the highest importance for surgeons to recognize this clinical fact, and adopt prophylactic treatment. In illustration of this principle, I will cite a case in my own experience, which strikingly affords an example of adopting some preventive means to eliminate this source of infection, so that, should any exciting cause arise to develop or produce a joint disease, the affection may not assume a tuberculous character.

In 1880 I removed from a young man, who resides in a neighboring city, a large cervical lymphatic gland, which had broken down centrally into a caseous mass. The operation was

a difficult one, and involved great danger, owing to a dissection which exposed the carotid artery, internal jugular vein, and the pneumogastric nerves, besides other important vessels and nerves. He recovered from the operation, and since the removal of the caseous mass has enjoyed excellent health. A year subsequent to the extirpation of the caseous abscess and gland I was called to treat the same patient, who was then suffering from a traumatism of the elbow joint, which resulted in a fracture of the olecranon and into the cavity of the joint. I was apprehensive lest a serious trouble might arise with this local injury and general diathesis. The fracture, however, repaired kindly, and the movements of the joint were in no way impaired. Upon recently questioning him as regards the utility of this joint, he tells me that he has no trouble with it, and has played lawn-tennis with this arm just as he was accustomed to before the fracture. It is not extravagant to say that the extirpation of the caseous abscess, with the chain of scrofulous lymphatic glands, from the young man's neck a year previous to the fracture into the elbow joint, removed, in his case, the chief source of general tuberculosis and tuberculous joint disease. Some of the caseous matter from the tumor was injected into a rabbit by Dr. Welch; but this experiment failed to give any positive result. However, a negative result in an experiment of this kind is of little value when it is considered how many conditions may arise to prevent the success of the experiment. A positive result would have placed the subject beyond doubt in the minds of all. Some very recent experiments by M. Arloing showed that inoculations from a caseous lymphatic gland were followed by tuberculosis in a series of guinea-pigs; but all the rabbits remained unaffected. When the caseous material was injected into the peritoneal cavity, the guinea-pigs died of tuberculosis, but the rabbits were still unaffected. This caseous material was taken from the neck in the case of scrofula occurring in a young man. Might not the fact that a rabbit was used in my case for inoculation thus explain the failure? In another set of experiments by M. Arloing, when he inoculated guinea-pigs and rabbits with the products of a strumous joint, both animals had tuberculosis. In still another series of experiments M. Arloing inoculated guinea-pigs and rabbits with the material from a cervical gland taken from a young woman who had no other symptoms of scrofula at the time. Both guinea-pigs and rabbits died of tuberculosis, and the patient also died a month afterward of acute miliary tuberculosis. The failure to produce tuberculosis in the rabbits at one time, and the success of inoculation at another time, can not as yet be explained; but this fact serves to illustrate the point that the failure in my own case in no way affects the question that bacilli were not present because tuberculosis did not follow the inoculation of the caseous mass from the young man's neck.

The patient's general health was improved by the operation, and the deformity was relieved, circumstances in themselves of great importance. But it can also be said that the extirpation of the caseous mass removed one of the chief sources of tuberculous joint disease and general tuberculosis. The young man's mother died of general tuberculosis; his brothers and sister have traces of the same dyscrasia; and with this clinical history, and with caseous lymphatic glands, there are the conditions which are known to favor the development of tuberculous joint disease and general tuberculosis. In the light which experimental pathology has thrown upon this subject, it is fair to assume that tuberculous joint disease and general tuberculosis would have resulted had the caseous lymphatic focus, with its bacilli, been present in the neck at the time of the injury to the joint.

It has been my custom for several years to remove all these cheesy masses whenever it is practicable. They are

sources of great danger, and should be extirpated under all circumstances. I have never had reason to regret an operation which had for its object the removal of these hot-beds for the cultivation and the multiplication of bacilli. I have, on the other hand, seen many cases where I have been convinced that early surgical interference might have rescued the patients from an untimely grave on account of general tuberculosis. Only recently I removed scrofulous glands with central caseous degeneration, and in the cavity of the abscess there were many ounces of pus. The abscess-walls consisted of a pyogenic membrane, and it is in this structure as well as in the pus itself that bacilli are found. The parts were removed as thoroughly as possible by dissection, and the cavity was scraped with a Volkmann's spoon; the wound was then packed with iodoform, and a drainage tube introduced for a few days. His general health, after the operation, rapidly improved, and he is at the present time in excellent health; the deformity is relieved and his mind is free from anxiety. This case is one of many illustrating the value of the principle which has been advanced in this paper, and at the same time is another example of the prophylactic measures which can be resorted to by the surgeon to avert tuberculous joint disease, which, with such conditions, is likely to follow any injury to a joint. Since tuberculosis has been proved to arise from the presence of these broken-down, cheesy, scrofulous glands, the importance of their removal is manifest when statistics show that, of the number of deaths from joint disease, over 50 per cent. are due to acute miliary tuberculosis, and over 25 per cent. to amyloid degeneration. The reduction of this high rate of mortality is to be attained by the removal of the sources of infection, which are caseous scrofulous glands.

To summarize, the line of argument is this: that—

First. Scrofulous abscesses are dangerous, because in them *Bacilli tuberculosis* may develop, and from these abscesses, as infective foci, general dissemination may proceed in the form of acute miliary tuberculosis.

Second. That tuberculous joint disease can produce general infection, or acute miliary tuberculosis.

Third. That traumatism may act as one of the many exciting causes to develop tuberculous joint disease, provided the conditions are favorable.

Fourth. That traumatism alone will not develop tuberculous joint disease except where certain conditions are present.

Finally, Mr. President and gentlemen, it is evident, from a study of this typical case, that much is yet to be learned in reference to the relationship between tuberculous joint disease and general tuberculosis. If the presentation of these microscopical slides—upon which may be seen the *Bacilli tuberculosis* which were found in the wrist joint, and the post-mortem specimens which were taken from the patient whose sad history has been discussed to-night—awakens an interest among the members of this association in this important topic in surgical pathology, the object of the paper will be fulfilled. It is to be hoped that during the coming year the attention of the profession may be directed to this subject, and that our next meeting will witness abundant testimony in the way of collective evi-

dence and clinical observation upon the principle which is involved in the title of this paper. The profession in this city as well as throughout the country are to be congratulated upon the magnificent facilities which will be in a few weeks afforded to them for investigating such subjects as the one which has occupied our attention this evening. All the knowledge which we possess upon this highly important surgical disease, affecting as it does thousands of individuals, has been derived from experimental work upon lower animals, and we are indebted to pathological laboratories for our only reliable guides. May the laboratory furnished and equipped through the generosity of Mr. Carnegie, as well as the forthcoming one to be furnished by the generosity of Mr. Vanderbilt, enable us to discover other important facts in connection with tuberculous joint disease and general tuberculosis. May these laboratories also afford places for investigating such diseases as cholera, yellow fever, and other malignant diseases to which the human flesh is heir. Thus will our knowledge be enriched, our standard of medical education be elevated, and the sufferings of humanity be alleviated. The gift of Mr. Carnegie last spring, and that of Mr. Vanderbilt this autumn, will enable American institutions to keep in the foremost rank in the advancement of medical science. In a recent address of Sir Spencer Wells he calls upon the profession of Great Britain to emulate the worthy example of Germany in establishing pathological laboratories which may be said to be fountains from which all our knowledge must flow. With the munificent gifts offered to the medical profession through the generosity of these private individuals, New York is destined, with its wealth of resource and its vast clinical material, to be the great metropolis of medical education and medical research.

ERRORS OF REFRACTION;

THE IMPORTANCE OF THEIR RECOGNITION AND CORRECTION IN EARLY LIFE.*

By H. E. MITCHELL, M. D.,

THRO, N. Y.

By errors of refraction are meant those anomalous conditions of the eye technically known as myopia, hypermetropia, and astigmatism. These, while forming a large percentage of the cases which the eye-specialist is called upon to treat, are but little known to the laity and but indifferently understood by the medical profession at large. Were the public better acquainted with these conditions, it is safe to say that we should see far less frequently than we do the rounded shoulders and contracted chests that are so common among the school-children of the present day, and which owe their origin largely to the stooping posture rendered necessary by imperfect vision. That defective eyesight, due to refractive errors, is markedly on the increase is a fact beyond questioning. I need not occupy your time in inquiring *why* this is true. The practical question of to-day is, What can we, as physicians, do to check this grow-

ing evil? In this brief paper I desire to present certain points, bearing upon this subject, for your consideration.

In order that we may clearly comprehend what a refractive error really is, let us consider the anatomy of the eye sufficiently to enable us to understand and recognize any departure from its normal condition.

The perfect or emmetropic eye is, as you know, nearly round, and, for five sixths of its extent, covered by three coats or tunics. The outermost, or sclerotic coat, is a dense, fibrous, opaque, unyielding membrane that serves to maintain the eyeball in its proper shape, and, at the same time, to afford protection to the more delicate structures within. Upon its integrity and unvarying shape depends the nice relationship of the various parts which make up this most complicated organ. The middle tunic, the choroid, is vascular and pigmented, and is connected with the inner surface of the sclerotic by a fine cellular tissue. From its rich blood-supply is derived the nourishment necessary for the support of the transparent media within, while its dark pigment serves not only to prevent the entrance of light, except through the pupillary opening, but also to absorb any excess that may have there entered. The innermost coat is the retina, and it is upon this delicate nervous membrane that all images of external objects are formed.

At the anterior portion of the eyeball, and continuous with the sclerotic, is the cornea, which, though fibrous, tough and unyielding, and of uniform thickness, is yet perfectly transparent. A short distance behind this is suspended the iris, which acts as a curtain, and is intended to permit only a proper amount of light to enter the eye through its central opening or pupil. Immediately in rear of this pupil is placed the crystalline lens. This is a double-convex body, measuring nearly a quarter of an inch in its antero-posterior diameter, and is retained in position by its suspensory ligament. It is elastic, and capable of having its focal power increased by the action of the ciliary muscles, producing what is known as accommodation. These ciliary muscles are firmly attached to the sclerotic at the junction of the iris and choroid, and possess contractile powers in a marked degree. The remainder of the globe is occupied by the vitreous body, a jelly-like, albuminous fluid, inclosed in a hyaloid membrane. Between the cornea and lens is a space containing the aqueous humor, divided by the iris into an anterior and posterior chamber, which communicate with each other through the pupil. The optic nerve—the special nerve of the sense of sight—together with the retinal vessels, enters the orbit from behind.

The opening thus formed in the sclerotic is funnel-shaped, and, though strengthened by numerous decussated fibrous bands, is the weakest point in the whole eyeball. The cornea, crystalline lens, and aqueous and vitreous humors are all transparent, and constitute what are known as the dioptric media of the eye.

When rays of light enter the normal eye from a distance of twenty feet or more, they are practically parallel, and, passing through the dioptric media, are brought to a focus, not only on the retina, but at its most sensitive part—a minute, circumscribed foramen, known as the fovea centralis, or yellow spot of Sömmerring. This is absolutely

* Read before the New York State Medical Association, November 18, 1884.

essential to perfect vision, and anything which interferes with or prevents parallel rays from being so focused must necessarily render the object looked at more or less indistinct.

In the three errors of refraction above mentioned we have three distinct ways in which this is brought about. These differ from each other in their *modus operandi*, but produce a common result, namely, *defective vision*.

In myopia, or, as it is commonly called, near-sightedness, we find an abnormal condition due to the elongation of the eyeball antero-posteriorly; and this change of shape is not caused by the bulging forward of the cornea, as is generally supposed, except in rare cases known as conical cornea, but is due to the posterior portion being lengthened or forced backward. Myopia may be acquired or congenital—congenital in the sense, at least, that weak lungs and throats and brain affections are transmissible from parents to children.

Carefully prepared statistics, compiled both in Europe and more recently in our own country, show a steady increase in the congenital form of this affection with each succeeding generation. The acquired form, however, is by far the more common and dangerous one, and its pathology should be carefully considered and clearly understood.

During childhood, the eye, like other organs of the human body, does not attain maturity. The sclerotic, which, later in life, becomes firm and unyielding, is at this period capable of being distorted by undue pressure, and this change of shape may be brought about by any over-exercise of the muscles which control the movements of the eye. Whenever the eye is accommodated for near work, as in reading or study, a corresponding amount of convergence takes place, due to the contraction of the internal rectus muscle, which, through its nervous center, acts in unison with the ciliary muscle by which the change in shape of the lens is effected. As the internal rectus muscle is attached to the sclerotic, it must exert, whenever it contracts, a certain amount of pressure upon the eyeball. This, if too long continued, causes the sclerotic to yield at its weakest point, namely, the optic-nerve entrance. Owing to their close relationship, the choroid is likewise forced back, dragging with it the delicate retina. A clear image can now be obtained only by bringing the object to be examined still closer to the eye, whereupon the increased convergence necessarily causes additional pressure upon the ball. Thus the very attempt we naturally make to overcome this defect only tends to increase and confirm it. Distant or parallel rays of light ought to be focused on the retina without any effort on our part; but, if the retina is too far back, this, of course, will be impossible, as only divergent rays can then be so focused. Hence it is at once apparent that the rational treatment would be to place a minus or double-concave glass of proper focal strength before the eye, which will render the parallel rays divergent. The internal rectus, and with it the ciliary muscle, will now be relieved from extra duty. The increased convexity of the crystalline lens will disappear, and undue pressure upon the eyeball will immediately cease. If this treatment is adopted sufficiently early in life, it is even possible that the natural

shape of the organ may be in part restored, though, as a rule, to check further deterioration of sight is all we may hope for. It should, however, be always borne in mind that myopia in the young shows a tendency to increase, and that, when the inner coats have undergone a certain amount of stretching, permanent and irremediable damage has been done. The moment acquired myopia is developed, the eye becomes a diseased organ, liable at any time, under excessive or improper use, to suffer, through retinal detachment, almost instantaneous blindness.

In hypermetropia we find the eyeball too short in its antero-posterior diameter; consequently the parallel rays are focused *behind* the percipient layer of the retina, and thus a blurred image is formed equally as in myopia. But there is this marked difference between the two defects. If the hypermetropia is not of too high a degree, the person is able to increase the convexity of his lens sufficiently to focus not only parallel rays, but even the divergent ones from a near object. Hence, in early life, while the lens is elastic and the muscles of accommodation are active, no special inconvenience may be experienced. So soon, however, as the child applies himself to his books, or the system becomes enfeebled by disease, the defect becomes at once apparent. The ciliary muscles, which up to this time have acceded without demur to the demands made upon them, now refuse longer to respond to this extra task. If the demand is persisted in, indistinct vision and painful and irritable eyes necessarily result. When the normal eye looks at distant objects, the muscles of accommodation are relaxed and the eye is at rest. Not so with the hypermetropic one. This eye must bring into play these muscles in order clearly to discern remote objects, and must still further make use of them sharply to define near ones. It is constructed to focus convergent rays only, and converging rays are nowhere naturally found except as coming from the interior of a myopic eye. Hence, as Jäger tersely puts it, "the fundus of a myopic eye is the only object under heaven which a hypermetrope is able to see without the correction of his ametropia." When this increased amount of accommodation necessary for close work is continued beyond a certain point, we frequently find that these muscles become spasmodically contracted and refuse to relax at all. Then results the condition known as *ciliary spasm*, which, inasmuch as distant objects are indistinctly seen, so closely simulates myopia that the careless observer may easily be misled. Still another complication may now present itself to add to the patient's discomfort. When speaking of myopia I mentioned the fact that increased accommodation was attended by a corresponding degree of convergence, but, inasmuch as in a hypermetropic eye there is always present a certain amount of accommodation, even when looking at distant objects, it follows that, when the hypermetrope wishes to examine anything close to him, an undue amount of convergence will direct the axis of vision to a point nearer than the object looked at. The image, therefore, will be received upon the retina at points which do not correspond, and diplopia, or a double image, will result. Any attempt to lessen this excessive convergence must be attended by a relaxation of the ciliary muscle, in

which case the lens becomes less convex, and no longer focuses sharply. In order, therefore, to avoid this duplicate image, one eye must be directed to the object, but, in doing this, another nerve-center is brought into play. This center regulates the lateral movements of the eye, and causes the external rectus of one and the internal rectus of the other, which heretofore have been antagonistic, to work in unison, and, therefore, as one eye moves outward the other simultaneously turns inward to a corresponding degree, producing a condition known as internal squint. Persons commonly look upon squint as simply an ugly deformity, but it is more than this. As a general rule, an eye that has squinted for any length of time is practically a worthless eye, for by its non-use, especially in early life, the retina has lost its sensitiveness, and, even though the deformity be removed by operative interference, the amblyopia will still remain. How important is it, therefore, for the future comfort of the child, that this refractive error receive early attention, and how easy, in this instance at least, to remedy nature's shortcomings and the attendant train of evils! If we give our patient a plus or double-convex glass of suitable focal strength, we at once enable him to relax his accommodation for distant objects. His ciliary muscles, no longer constantly contracted, regain their normal tone. The pain and irritability vanish, for the *cause* has been removed, and the eye becomes practically a normal one, capable of doing its full share of work without danger or discomfort to its owner.

The correction of the remaining refractive error, astigmatism, is somewhat more difficult, presenting, as it often does, many complications which require great care and thoughtful study before we can thoroughly master them; but which, when once understood, afford a most satisfactory proof of the great advance that the science of ophthalmology has made in modern times. Astigmatism, as ordinarily met with, consists of a variation in the shape of the cornea from its normal spherical form. It may be elongated in one diameter and shortened in another; or it may be longer or shorter in both, but in a different degree; or normal in one, and longer or shorter in the other. In any case the rays of light emanating from a given point and passing through the cornea are refracted unequally, and are not reunited into one point upon the retina. The image must consequently be blurred, and, in the involuntary effort that the person makes with his accommodatory apparatus to focus for each of these different meridians, the ciliary muscles are so constantly called into play that they become fatigued from excessive action, and asthenopia is added to the patient's discomfort. Strictly speaking, astigmatism is not a separate error of refraction, but rather a combination of the two errors before described. If the cornea projects more than is normal, the eye is just as truly myopic as if the posterior portion was forced backward, and hypermetropia equally results, whether the eyeball is flattened anteriorly or posteriorly. The glass, however, which will correct the simple hypermetropia or myopia will not answer for the hyperopic or myopic astigmatism, for it must be remembered that only a *part* of the cornea requires its refraction to be changed. Take, for instance, a patient who is myopic in one meridian, but hyper-

metropic in the other; now place before such a one a minus glass capable of correcting the myopia, and what is the result? The myopic meridian becomes normal, but the hypermetropic one is rendered still more hypermetropic, and nothing is gained. For astigmatism, then, the glass required will be one that represents a section of a cylinder and not of a sphere. The rays of light, in passing through such a glass, will only be refracted in the plane at right angles to its axis, and, by a combination of these cylindrical lenses, we may use both a plus and minus glass for the same eye.

One peculiarity of this defect lies in the fact that it is only capable of recognition and correction by one who has made eye matters a special study. A person who is nearsighted may select a glass from an optician's stock adapted to his degree of myopia; and even the hypermetrope, if his case is uncomplicated with ciliary spasm, may not err in his selection to any serious extent. Not so with one who is astigmatic. Each case must be worked out by itself, and corrected accordingly.

Among the masses there is undoubtedly a strong prejudice against the early use of spectacles or eye-glasses; but, as the subject becomes more fully understood, this prejudice will melt away. You would think a surgeon sadly remiss in his duties who attempted to treat a fractured limb without a splint, or a diseased hip without extension, and yet you see cases in your daily practice that stand in urgent need of the relief and benefit that the proper glass alone can afford. One may observe on the streets to-day ten children wearing glasses where only one was noticeable a few years since; but where one is seen to-day ten more ought to be seen, for it is safe to say that, if suitable glasses were prescribed before the age of twelve years, the number of persons affected with refractive errors would soon begin to decrease, and the amount of inconvenience and discomfort, and even actual suffering, would rapidly be diminished. The practical conclusion, then, is: let the eyes of the young be examined, and, if found defective, provided with suitable glasses so soon as their possessors are old enough to wear them with safety, and until then do not allow excessive reading or study.

The question now presents itself, How shall the general practitioner, who has paid no special attention to eye matters, recognize these defects? In reply I would suggest, Provide yourselves, first, with an ordinary set of test-types and lines, and, secondly, with an *optometer*.

With the use of the former, doubtless, you are all more or less familiar; but regarding the latter much less is generally known. Yet I have found it of so much assistance, not only in verifying a diagnosis but also in saving time by at least approximating to the required lens, that, with your permission, I will exhibit one and explain its uses.

So far as I know, this form of this instrument is not mentioned in any work on ophthalmology. Neither do I find it advertised or shown in the catalogue of any instrument-maker. I do not even know to whom the credit of its discovery belongs. The one before you was modeled after one obtained, more than a dozen years ago, from the Royal Ophthalmic Hospital in London, and is the simplest and most serviceable form of the instrument that I am familiar

with. It consists, as you see, of a straight rod two feet long by three quarters of an inch wide and one quarter of an inch thick, graduated in inches and fractions thereof. At one end is firmly attached a semicircular metallic frame in which an ordinary ten-inch double-convex lens is placed. A small clamp, so arranged as to slide back and forth upon the stick, contains a card printed in No. 1 or brilliant type. Closing one eye and placing the ten-inch lens before the other, a young normal eye should read the print with ease as it is moved along from the three to the ten-inch point. If one can not read out as far as the ten point, but can read nearer than the three point, myopia is indicated. If not as far as the ten point and not as near as the three point, astigmatism is probable. If beyond the ten point, hyperopia certainly exists; and if to the ten point but not nearer than the five point, presbyopia may be assumed. In the cases of children we can, of course, eliminate this last defect. When more than one refractive error is present we can not recognize so easily or estimate so closely; but even then, by careful observation, the exceptions become nearly as instructive as the rules. Suppose a patient reads easily from the three to the fifteen point. To find the glass which he would require to correct his hypermetropia, we multiply the standard point ten, at which he ought to read, by fifteen, the point to which he actually does read, and divide the product by the difference between the two points: e. g., $10 \times 15 = 150 \div 5 = 30$ —a *plus* $\frac{30}{10}$ glass will therefore correct his manifest hypermetropia. Again, if he reads nearer than the three point and less than the ten point, say from two to six, we probably have myopia to deal with, and we make our calculation as follows: multiply his punctum remotum, which is six, by the standard point, ten, and again divide by the difference: e. g., $6 \times 10 = 60 \div 4 = 15$ —a *minus* $\frac{15}{15}$ lens will practically correct his nearsightedness. In astigmatism this instrument is of no service further than that it enables us to arrive at the diagnosis by exclusion. In this defect we depend principally upon our ophthalmoscope and test-lines. In presbyopia we may take the point five as a standard for the near point and calculate as before. If a person can not read nearer than the eight point, then $5 \times 8 = 40 \div 3 = 13$ —a *plus* $\frac{13}{13}$ will therefore be suitable for his reading-glass.

I do not intend to convey the idea, by what I have just said, that any one having a set of test-types and an optometer would be justified in assuming that he was duly equipped and qualified to prescribe glasses for his patients. Those of us who have devoted special study to this branch know that it oftentimes requires all of the many means at our disposal to arrive at a correct solution of the difficulty; but I do think that, by a little attention to and practice with these two inexpensive and easily understood appliances, any physician may satisfy himself whether or not his patient is in need of an examination at the hands of an oculist, and will have it in his power to contribute largely to the solution of this difficult problem presented to us—viz.: *What shall we do to lessen the rapidly increasing number of defective eyes among children?*

REMARKS ON EXTIRPATION OF THE KIDNEY, WITH CASES OF NEPHRECTOMY FOR PYONEPHROSIS AND NEPHROTOMY FOR RUPTURE OF THE KIDNEY.*

By ROBERT F. WEIR, M. D.,

SURGEON TO THE NEW YORK HOSPITAL; PROFESSOR OF CLINICAL SURGERY,
COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

In September of last year a young woman, aged twenty-three, came under my charge at the New York Hospital for a tumor in the right hypochondriac region, of which she gave the following history:

In 1876, seven years previously, she had a severe and obstinate attack of cystitis, which lasted, in spite of all treatment, for two years, when, at the Roosevelt Hospital, a vesico-vaginal opening was made to place the bladder at rest. This gave such relief that at the end of a year she had the opening closed by an operation, believing herself fully cured of the cystitis.

But this proved not to be true, for the symptoms reappeared, and six months later the wound was reopened. In September, 1880, the fistula, which had become contracted, was enlarged at the Woman's Hospital. After remaining there for some time with moderate improvement, she left that institution, but came back again in September, 1882, the irritability of the bladder being worse, if possible, than ever before. The urethra at that time was button-holed, as it is called by Dr. Emmet; in other words, an incision was made along the lower floor of the urethra, and the superabundant mucous membrane drawn out and removed. But shortly after this she had such severe pain that it led to an examination under ether for stone. No calculus, however, was found in the bladder, but it was observed for the first time that there was a tumor in the right upper part of the abdomen. Thinking this was possibly due to the presence of a calculus in the ureter, a sound was introduced into the right ureter through the vesical fistula, which had been further enlarged, but with negative results. I believe that an operation for removal of the kidney was then suggested, but the patient went out of the hospital, and afterward came under the care of Dr. Peters, at St. Luke's Hospital, where an exploration with the hand in the rectum was made, and also an endeavor to catheterize the ureters. No positive evidence was obtained by these examinations. When the patient entered my ward there was felt on the right side of the abdomen a smooth, but somewhat painful, tumor, which stretched from the edge of the ribs nearly to the crest of the ilium, and which measured some four inches in its transverse diameter. This was believed, from its situation and history, to be a kidney in a condition of pyonephrosis. Aspiration having failed in extracting any pus, and, in consequence of the report furnished that the previous rectal examination had gone against the renal nature of the tumor, the patient was again etherized, and, by the small and skillful hand of Dr. Sabine, the regions of the kidneys were carefully examined, and the tumor proved to be, as thought, a diseased kidney. At the same time, by strongly holding aside the large fistula in the bladder, the mouths of the ureters could be seen and explored their whole distance by flexible metallic sounds. There was no calculus to be discovered, and, while the urine from the affected kidney was flocculent from the admixture of pus, that from the left or sound side was clear and normal. On each side it was voided in intermittent jets.

The patient's general condition was fair, though her annoyance from the continued urinary leakage was great. During the time she was kept under observation before the operation the urine was repeatedly examined, showing a satisfactory spe-

* Read before the New York Surgical Society, December 9, 1884.

cific gravity and absence of casts. This increased the confidence that the left kidney was in a good condition, in spite of the statement that she had had several convulsions during the past three years. During the two weeks prior to the operation her condition began to fail, less perhaps from inflammatory than from mental causes. She was urgent for surgical interference, though aware of the danger of the procedure. An operation possessed no terrors for her, as she had already been anesthetized twenty-three times since her cystitis began. Nephrectomy was performed November 3d, under antiseptic precautions, by a lumbar vertical incision, starting just below the twelfth rib, three inches from the spine, and running to the crest of the ilium. A second, transverse, cut was made from near the top of the vertical one, outward along the edge of the ribs, nearly five inches long. This gave large access to the kidney without opening the peritonæum, which was seen at the outer part of the transverse incision, but sunk out of the way by the semi-prone position of the patient. On exposing the dense fatty capsule, it was scratched through and the kidney partly brought into view. An aspirator showed the situation of an abscess, which was opened to determine whether simple nephrotomy with drainage would suffice. Exploration showed that it was a small cavity, and apparently others existed which did not open into the first one; extirpation was therefore proceeded with. It was at once found that the fat capsule was intimately adherent to the kidney, the true fibrous envelope of the organ was therefore split open, and enucleation accomplished with rapidity everywhere except over the anterior surface of the kidney, where the peritonæum was felt to be very thin. The pedicle was finally reached, and a loop of strong ligature silk cast around the kidney, carried to its base, and tied, after which the kidney was removed. A gush of venous blood ensued, which was only partly arrested after repeated seizures with long force-pressure forceps, but was finally controlled by stuffing the wound full of sponges and turning the patient on her back. The shock was profound, and all the measures to produce reaction were resorted to, such as heat, stimulants, the application of Esmarch's bandages to the limbs, and saline transfusion. The latter, repeated twice to a total amount of twenty-two ounces, gave rise at first to great improvement in consciousness, pulse, and warmth of body, and up to 10 o'clock P. M. she appeared to rally, but then failed steadily, and died at 2 A. M., ten hours after the operation.

The autopsy showed that the hæmorrhage came from a vein of considerable size, 1.5 centimetre above those secured by the ligature and forceps. The fibrous capsule of the kidney was so closely adherent to the condensed fat without that it could be removed only by a close dissection. The peritoneal cavity was not invaded. The left kidney was larger than normal, and, microscopically, the convoluted tubes contained a good deal of fat in their epithelial cells. This change was quite general.

The removed kidney, slightly larger than natural, was riddled with abscesses, which did not communicate one with the other, and only partially with the pelvis. There was no serviceable kidney tissue to be found in the organ.

REMARKS.—The operation of nephrectomy, first resorted to intentionally by Simon,* in 1869, has now been performed, so far as I have been able to investigate, some one hundred and fifty-two times,† with a gross mortality of seventy-six

deaths, or fifty per cent. Nor has the mortality decreased in the last fifty cases, as might have been expected. It is, therefore, yet one of the gravest operations in surgery.

It has been employed for the removal of healthy as well as of diseased kidneys. In the former category may be placed the extirpation for ureteric fistula, for floating kidney, and for laceration of the organ. In the latter, the lesions may be embraced generally under the heads of obstructions, suppurations, and tumors of the kidney.

For wounds or lacerations the kidney has been extirpated five times (Brandt, Marvand, Cartwright, Rawdon, and Bruns), with two deaths. For fistulæ communicating with the ureter, and situated either in the vagina or the uterus, or communicating externally, there have been reported nine cases, with two deaths. For floating kidney sixteen cases are recorded, with six deaths—fourteen by laparotomy and two by the lumbar incision. The mortality for this condition is so high that it would of itself discourage the operation for an affection which does not threaten life. But, since the introduction by Hahn of the plan of fixing the loose kidney after exposure by a vertical lumbar incision, by stitching its capsule to the muscular or skin tissues, the use of nephrectomy for this reason will probably be abandoned. The operation of nephrorrhaphy has been performed sixteen times with but one death—due to a fault of the operator—and with generally satisfactory results. In the case operated on in this way by myself, and published in the "New York Medical Journal" for February 17, 1883, the subsequent history was encouraging, though several months afterward the patient had a severe attack of jaundice, and some symptoms indicative of a perinephritic inflammation. These passed off, and she has recently reported herself as much benefited by the operation. The appreciation of this method is, however, not yet definite, since too short a time has elapsed to determine whether the fixation produced is truly a permanent one.

Although hydronephrosis is one of the conditions for which extirpation of the kidney is done, yet, according to the excellent remarks of Billroth* on the operation (from whom in part my data are obtained), the only diseases demanding the operation are neoplasms and suppuration of the kidney. It is significant that nearly one third (twelve) of the cases of nephrectomy for hydronephrosis have been accomplished through an error of diagnosis, being mistaken generally for ovarian cysts.

The death-rate, whether from this cause or from the inherent difficulty of the removal of a hugely distended kidney, is very large, for, in the twenty-one cases collected by Staples, ‡ where nephrectomy was employed, there were by laparotomy seventeen cases with eleven deaths, and by the lumbar incision three cases with one death. In contrast to

creased to one hundred and thirty-two. Subsequently S. W. Gross collected one hundred and forty-three cases, to which I have added three performed by Dr. Thomas, two by Thornton, and one each by Boothby, Halsted, Morris, and myself, which makes the total one hundred and fifty-two.

* "Ueber Nierenextirpation," "Wien. med. Wochenschrift," Nos. 24, 25, 26, 1884.

† "Hydronephrosis; A Study of Seventy-one Cases of that Lesion," by G. A. Staples. "Jour. of the Am. Med. Assoc.," April 19, 1884.

* Wolcott, of Milwaukee, was perhaps the first to remove the kidney, in 1860, for a carcinoma. The patient died on the fifteenth day.

† The original collection of one hundred cases by Harris, in the "Am. Jour. of the Med. Sci." for July, 1882, was augmented in Bolz's thesis to one hundred and twenty-one cases, which Billroth further in-

this mortality are the striking results obtained by incision and drainage in sixteen cases of this affection collected by the same observer, in which there were fourteen cases of recovery and two deaths. In some of the recoveries it is true fistula resulted, but were reported as diminishing or as not troublesome. In this connection I would refer to the case of hydronephrosis where nephrotomy was successfully used by me, and which was presented to you by Dr. Peters in his paper on Hydronephrosis* before this society February 28, 1882. Bergmann has also stricken out hydronephrosis from the list of diseases requiring nephrectomy for their treatment.

From the foregoing remarks it will be seen that the principal interest connected with the operation of extirpation of a kidney is associated with tumors and suppurative lesions of that organ. In respect to the nature of the neoplasms for which the kidney has been removed, it is found, from the twenty-seven cases collected in Homans's† article on the subject (to which I have been able to add two cases by Thomas, and one each by Vercelli, Little, and Halsted, making a total of thirty-two cases), that they have been sarcoma eighteen times, carcinoma nine times, adenoma once, fibroma once, and of doubtful nature three times. Twenty-two of these patients died, or nearly sixty-nine per cent. This mortality, so much greater than in any other lesion for which nephrectomy has been performed, will attract attention at once, and the inquiry will naturally arise, What has been the outcome even in the successful cases? This point has been well considered by S. W. Gross in the "Medical News" for June 9, 1883, who states that the disease returned in 31·5 per cent. of the cases, and that the average duration of life was rather less than twenty-four months. Taking this fact in connection with the statement of Rohrer and Roberts that the average duration of life without operations is two years and a half for adults, and of Dickinson that in nineteen autopsies, in cases of malignant disease of the kidney, in sixteen cases secondary growths were found, the operation of nephrectomy is at first sight to be discouraged. It may be, however, somewhat premature to pronounce upon this question dogmatically until experience is increased, especially since two of the patients remained well after the operation for twenty-one and thirty months respectively. It certainly seems correct to urge that only small growths should be submitted to the operation, on account of the risks of hæmorrhage and of relapse which more decidedly belong to the larger tumors, and from the fact that in such cases the safer lumbar incision can be employed, for, in thirty-two cases, twenty-five patients were treated by the abdominal incision, of whom twenty died, and seven by the lumbar incision, of whom two died.

By the foregoing process of exclusion it is fairly well shown, I think, that the principal, if not the sole, condition in a diseased kidney that justifies a nephrectomy is a suppurative process. Under this head are embraced abscesses of the kidney, whether single or multiple, or whether in the pelvis or in its substance, or simply pyelitis from cystitis or from renal calculus, etc.

Of such cases Billroth, quoting from Bolz, gives forty instances with eighteen deaths: this I have been able to increase to forty-seven cases, but, from a private communication from Dr. S. W. Gross, I can now present a total of fifty-eight cases, and from an analysis of this number I shall endeavor, if possible, to furnish a due appreciation of some of the mooted points connected with this domain of renal surgery.

The first, and probably one of the most important, considerations in connection with the operation of nephrectomy is the question of not only the existence of a second kidney, but also of its condition. Given abundant pus with certain renal elements in the urine (and even these may be utterly absent, if the abscess does not communicate with the pelvis of the kidney), to which kidney do these characteristics point? We may not always have a tumor to determine this, and this notably in some instances of renal calculi, but, even though a latero-anterior tumor presents itself, yet the status of the second kidney should be determined if possible. Repeated examinations of the urine with absence of casts and epithelium may contribute toward a certainty, but, since we find, even with a presumably sound kidney, so frequently suppression of urine following a nephrectomy (possibly due to a weakened heart from shock), it is not to be wondered at that endeavors have been made in various ways to arrive at positiveness in the solution of this difficult point. One of the greatest arguments made in favor of the abdominal section is the ease with which thereby the existence and general condition of a second kidney is determined. This is a serious consideration, and is brought home to us, for in the cases of nephrectomy performed in this city—viz., those of Peters, Wright, Wylie, Polk, Lange (2), Thomas (3), Halsted, and my own, in all eleven cases with nine deaths—in two there was but a single kidney (Polk's and Lange's). In the first there was congenitally but one kidney, and that abnormally situated in the iliac fossa, as in the specimen of a left kidney, the right being normal, which I can now show you, which was removed from a cadaver by our pathologist, Dr. Peabody, who states that it is the only example of this anomaly met with by him in over two thousand post-mortem examinations. The single kidney is found about once in five thousand bodies; hence such a surgical complication can fairly be disregarded.

In Lange's case of tumor of the kidney the other kidney was found to have been converted by previous changes into a shriveled, caseous cyst.

Undoubtedly the abdominal incision would have permitted the avoidance of this surgical error, but when we reflect on the rarity of such complications, and on Bergmann's statement that in forty cases of nephrectomy for pyonephrosis only once was the other kidney damaged enough to be useless, and also on the mortality that has followed this method of operation for suppurative lesions of the kidney, we are forced to look about for other means than laparotomy for help in this connection. This mortality is as follows: Of the fifty-eight patients referred to, thirty-one recovered and twenty-seven died; sixteen of these were treated by the abdominal incision, with ten deaths, or a mortality of 61·5 per cent., and forty-two by the lumbar

* "Med. Record," May 6, 1882.

† "Boston Med. and Surg. Jour.," January 24, 1884.

incision with seventeen deaths, or a mortality of 42·8 per cent. Separating these cases still further it is found that fourteen of them were for calculous pyelitis, with four deaths, and that of this number only one was treated by the abdominal section, with recovery. This shows clearly that, unless, as was the fact in this case (Wright's), the diseased kidney was at the same time a floating or abdominal kidney, the lumbar incision is by all odds to be preferred, not only because it is safer but because it also permits the simpler extraction of the calculus, and with less risk from the possible urinary fistula that may result. Taking now this form of kidney lesions from the comparison of the abdominal and lumbar modes of nephrectomy, we further find in the forty-four cases remaining that the abdominal incision was employed fifteen times with ten deaths, and the lumbar twenty-nine times with thirteen deaths, again showing the superiority as regards mortality of the posterior or extraperitoneal incision. It is true that a wonderful success has been shown by Thornton in ten nephrectomies of all kinds by the anterior incision without a single fatal result, and Tait has also from a smaller number given his authority in favor of the method; but, on the other hand, it is to be said that a number of these cases were errors in diagnosis and unintentionally attacked, many were hydronephroses, some were tumors, and but few suppurative lesions. Czerny, who of all surgeons has had the largest experience, having removed eighteen kidneys, strongly urges the advantage of the lumbar incision, and Billroth, in comparing the two methods, advocates the posterior operation, which he says should be used, moreover, when "in doubt." The conclusion is therefore evident that for large tumors, which in my judgment negative the operation, and where not only the size, but the amount of hæmorrhage, is to be thought of, the abdominal method is more favorable; but for small tumors, or for pyonephrosis of all kinds, with, in the last class of cases, the risk, always great, of their rupture and infection of the peritoneal cavity, this incision is not to be selected. In addition to these reasons there is another, which has recently been set before us by Lucas* in his excellent paper on this subject, that many cases of suppurating kidney can best be treated after their exposure by the lumbar method, by incision and drainage, and, after these measures have failed to cure the patient, then extirpation can be effected with much less risk to life. He gives six cases, of which all recovered, in which nephrectomy was done in this manner. I confess that, until the logic of his statistics and personal observations had convinced me, I had entertained a reverse idea from an experience obtained in Roosevelt Hospital in 1878. I had then a renal tumor to deal with on the left side, which, after exposure by a lumbar cut and aspiration, followed by an incision to evacuate a large amount of matter, was treated by drainage, a consultation of my colleagues having decided against nephrectomy. The patient did well for a while, but eventually succumbed to a subperitoneal phlegmon, which started from the kidney and descended to the pelvis. I have since watched the prog-

ress of two sinuses formed from similar kidneys, and they have each completely recovered without nephrectomy, and last week nephrotomy and drainage was done in a similar condition by my associate, Dr. Abbe, with so far satisfactory results. All these cases tend to present the claims of a lumbar incision in strong light. The question which therefore we come back to is, whether the determination of the existence and condition of the second kidney can be reliably arrived at. This is truly not easily answered.

Tuchmann was one of the first to continue and employ an instrument like a lithotrite which was intended to occlude at will one of the ureters from within the bladder. It failed to work. Later, when this question obtruded itself in the minds of surgeons, Glück suggested that a preliminary incision should be made in the loin down to the diseased kidney, and its ureter clamped while iodide of potassium was administered, and the urine of the other kidney was extracted from the bladder and tested for iodine. I do not know that this procedure was ever put into practice. Lange suggested an incision over the sound kidney to permit a digital examination of it. Catheterization of the ureters, practicable though difficult in the female, has been called into use, and in that sex affords some hope of certainty. In the male, however, unless through a perineal opening to guide the finger and catheter, the chances are much against its efficiency. Polk,* in his endeavors to avoid a repetition of his case, has devised a clamp, one blade of which is to be passed into the male or female bladder and the other into the rectum so as to compress the ureter between them. This seems rational, and may yet prove of service, though in the male, as for catheterization of the ureters, a perineal opening would probably be necessary. Struck, in 1882, by the efficiency of Davy's rectal rod in controlling the circulation of the iliac artery in an amputation at the hip joint, I thought, by broadening this rod a little, so as to compress more space, that the ureter might at the same time be occluded, and it has proved satisfactory in the single case in which I have yet employed it. In a recent number of the "British Medical Journal" is an account from Mr. Davy himself, in which he states that he suggested this application of his rod in 1873, and that he has recently used it with success.

Another expedient which attracted me yet more favorably is that presented by Dr. H. B. Sands, and is based upon his experience of compressing the iliac artery for over an hour with the hand in the rectum. This surgeon advises that the same means be used to obliterate the ureter temporarily, while the secretion from the other kidney thus separated is collected by a catheter in the bladder and examined. Unfortunately for absolute accuracy the ureter is so soft and yielding as not to be readily recognized by the fingers as it crosses the edge of the pelvis, yet several trials on the cadaver have shown me that in every instance compression of the artery with two or three fingers at the same time occludes the ureter. This method has another great advantage, which is this, that, unless the narrowing of the rectum, which occasionally is met with is present, the hand, if small enough—i. e., less than 8·5 inches in circumference—can be

* "On the Surgical Diseases of the Kidney and the Operations for their Relief." R. Clement Lucas, "British Med. Jour.," September 29, 1883.

* "New York Med. Jour.," February 17, 1883.

introduced up to the sigmoid flexure, and thereby be allowed sufficient excursion to permit reaching the lower portions of the kidney of each side.

Reference must also be made to the device of Silbermann,* who introduces through a large catheter little rubber bags, attached to slender flexible catheters, which are subsequently filled with quicksilver by a syringe, and are intended to plug by their weight the mouths of the ureters. I have not been able to obtain any good results from this instrument, which is now shown to you.†

In a doubtful case, not otherwise to be solved, an exploratory or small abdominal incision, as advised by Tait, could be made. Billroth, it will be remembered, made such incisions twenty-seven times without harm in pyloric cancer, by which he determined the inoperable nature of the disease. The following cases of abscess resulting from laceration of the kidney illustrate the advantage of this procedure:

LACERATION OF KIDNEY; ABSCESS; NEPHROTOMY; RECOVERY.

—Mary Q., a young married woman, aged twenty-six, was admitted October 6, 1884, to the New York Hospital, with the history of a miscarriage in May last, with persistent uterine hæmorrhage until August. During this time she had had repeated attacks of inflammation in the abdomen, the last of which, in August, confined her to the bed. After this she was well until her last menstruation, September 15th. After her usual flow had lasted five days, she began to have fever, with nausea and pain in the abdomen. She was admitted at first to the medical division of the hospital, where a tumor was discovered just above the right ilium, into which a hypodermic needle was inserted and a syringe of pus withdrawn. Her temperature ranged from 100° to 103°, and her urination was frequent and painful, and microscopically contained pus, casts, and blood. On interrogation she positively denied receiving any injury. When first seen the tumor extended from the edge of the liver, whose dullness was continuous with that of the tumor, to nearly the crest of the ilium, and in its transverse diameter it was nearly five inches broad, painful on pressure, smooth and resisting. A hypodermic needle failed on a second trial to extract anything but pure blood. With the history given the nature of the tumor was felt to be doubtful, as exploration *per vaginam* disclosed the adjacent parts uninvolved, and it was therefore determined to delay until the evidence of suppuration was given by aspiration or otherwise. Although her temperature range was, as before, as high as 103° F., her general condition was comfortable. Three days later another puncture in a different locality resulted in the same extraction of blood, but on the fifth day pus was obtained by the same test, the urine being, during this time, nearly normal in character. She was etherized, and in the class of students present was the patient's physician, who furnished the important detail of a kick received by her some ten days prior to her admission to the hospital, from a person whom she was unwilling to implicate, whence her repeated denials when questioned. After the injury there was for two days perceptibly bloody urine.

In the hope of the abscess being a perinephritic one, an exploratory incision was made over the outer edge of the tumor, between the middle of the crest of the ilium and the ribs, so that if it were such, it might be possible to keep behind the

peritonæum, and, if it were not that, the benefit of an ordinary abdominal exploratory section might be enjoyed. Before the peritonæum was fairly reached, the wound permitted a conclusion against an abscess of any size exterior to the kidney, and the finger was therefore carried into the abdominal cavity, and the enlarged, and in spots softened, kidney easily and quickly recognized. The abdominal wound was closed by silk sutures, and the patient turned over, and the usual incision from the ribs to the ilium, along the quadratus lumborum, made, the kidney reached, exposed, and found so softened that with a thrust of the finger a cavity was opened, containing considerable grumous bloody pus, on evacuating which a jagged rent could be felt running toward the free border of the kidney and downward, which was evidently a laceration from the kick. A large-sized rubber tube was inserted into the cavity of the abscess, and the wound antiseptically dressed. The temperature fell at once, and the patient did well subsequently, with a free discharge from the posterior wound for forty-eight hours, when it rapidly decreased. Ten days later the tumor had much diminished in size, but at its lower portion was yet tender. From the wound a probe was crowded in this direction, and gave exit to a small quantity of blood and pus, and over the probe a small rubber drainage-tube was carried, and by the thirteenth day the temperature was normal. The anterior wound healed promptly, the sutures being removed on the fourth day. The posterior wound was entirely healed November 6th.

Now, December 5th, there is felt some hardness anteriorly at the region of the lower part of the tumor, but above normal intestinal resonance. It looks as if there had been some perinephritic inflammation as well as renal.

Incidentally in these remarks the advantage of nephrotomy over nephrectomy has several times been alluded to or illustrated. I beg now to call attention to a further extension of renal surgery of equal interest to us all. I refer to the treatment of calculous suppression of urine.

Roberts, of Manchester, had shown that the diagnosis of such cases was not always difficult, that a history of renal colic of one side at some previous time, with a recent similar attack on the other side, with slight or intermittent discharge of urine of low specific gravity, pointed clearly to the difficulty which terminates nearly always fatally in from six to ten days. In an article on Renal Calculi, published by me in the "New York Medical Journal" of August, 1880, the suggestion was made that as the arrest of calculi took place as a rule either within the first three or four inches of the ureter, or at the vesical end, relief was to be afforded either by an incision in the loin, into the pelvis of the kidney, or the distended ureter, or that by the hand introduced into the rectum the calculus might possibly be squeezed into the bladder, if sufficiently small.

In the "British Medical Journal" for March 8, 1884, Mr. Bennett May recommends nephrotomy for this same purpose, though he had never carried the project into execution.

Lately Mr. Morris, in the "American Journal of the Medical Sciences" for October, 1884, suggests the use of a perineal opening into the bladder to permit its exploration and the detection of a renal calculus when impacted at its vesical outlet, and gives a plate of an elongated gun lancet to accomplish the incision of the vesical tissue covering the calculus. I have been on the outlook for a case in which I could put into operation my surgical convictions on this sub-

* "Berl. klin. Wochenschrift," No. 34, 1883.

† Silbermann shut off the ureter twenty-seven times in the ten women and five men upon whom he employed his instrument.

ject, but its demonstration, as far as I can learn, has only been accomplished by Bardenheuer, of Cologne.

This surgeon, in a case of complete anuria with threatened acute uræmia from calculous occlusion of the right ureter, subsequent to destructive suppurative of the left kidney, cut down upon the right kidney by the usual vertical incision in the loin, and supplementing this by another incision parallel to the crest of the ilium. This gave a free exposure of the kidney, which was separated from its fatty capsule along its anterior face until the pelvis and ureter were reached. A calculus was felt in the ureter, near the kidney, the size of a bean; this was cut open, removed, and the finger passed upward into the pelvis of the kidney, where four other small calculi were found and extracted. The ureter was then sewn up, and the wound packed with an antiseptic dressing. The patient recovered.

THE INCISIONS.—The method resorted to in the case of nephrectomy given in this paper seems to be the best of the lumbar incisions, as it affords the greatest amount of extraperitoneal space. The usual vertical one, running from just below the twelfth rib to the crest of the ilium, along the external border of the quadratus lumborum muscle, or about three inches from the spine, affords ample room for a nephrectomy of a normal kidney, or for a nephrotomy, but, when the organ is much increased in size, additional room is desired. Enlargement of the wound upward to the twelfth rib, or by removal of the rib, is highly injudicious, as has been shown by the dissections of Holl,* who showed that the pleural cavity, in nearly every instance in the examination of sixty cadavers that he examined, descended as low as the first lumbar vertebra, and that the greater part of the last rib is lined by this serous membrane. Even when the rib is wanting the pleura comes down to the ligamentous tract which supplies the place of the bone. Lange has since shown that not infrequently the pleura comes even lower alongside the spine. In the only fatal case of nephrorrhaphy (Ceccarelli's†) the kidney was attached not only to the wound, but also stitched to the twelfth rib by sutures passed around it. Acute septic pleurisy carried off the patient. Increased space can often be obtained, and safely, by cutting across the middle of the quadratus up to the spine. Also the ribs can be strongly raised by retractors. Czerny several times removed the kidney by a simple transverse incision running parallel to the ribs and just below them outward for from six to eight inches. In my own case there was plenty of space created by the cross-incision, like an inverted L, starting from the upper part of the vertical one and longest in its skin divisions. This is well shown in the specimen presented for your inspection. The peritonæum was seen, but it was kept out of the way by the semi-prone position of the patient. This line of incision is also advocated by Lucas. In a comparatively healthy kidney, or where the organ is the seat of a neoplasm, there is but little involvement of the fat capsule, and it can easily be torn or separated from the kidney. In inflammatory lesions, however, this manœuvre can not be utilized, and the capsule proper of the kidney must be incised, and the enucleation accom-

plished under the membrane. This may add to the hæmorrhage, but it is often impossible to do otherwise. The specimen shows this very markedly. Lucas has also advised, where the hæmorrhage is severe after the ligature and ablation of the diseased mass, not to spend time in endeavoring to secure the bleeding points by ligature or forceps, but to plug the wound and check it in this way. I was struck too late in my own unfortunate case with the efficacy of this measure. After several attempts to seize and tie the source of hæmorrhage, found after death to be from a venous trunk above the pedicle, I plugged the wound, as will be remembered, and turned the patient on her back, when very little pressure sufficed to staunch the flow. Had this been done earlier the issue might have been different. Special care must be taken not to cut too close to the ligated pedicle. The application of a straight or curved forcipressure forceps beyond the ligature prior to the ablation is to be advised, to guard against this mishap.

Of the abdominal incisions there are two: (1) the median, running three inches above and below the umbilicus, but less, however, in women with lax bellies. Kocher, however, began his at the xiphoid appendix and ended it at the navel. (2) That of Lagenbuch, along the outer edge of the rectus in the linea semilunaris. By this latter incision the colon is promptly seen, and should be turned to the inner side so that its posterior or outer mesenteric fold can be cut through. This insures less hæmorrhage, and avoids partially a risk that Bergmann ascribes to the abdominal incision, viz., subsequent gangrene of a portion of the intestine from interference with its circulation. When the kidney has been removed Sir Spencer Wells advises the rent in the peritonæum to be closed by sutures; this can not always be done, as the edges are often torn and irregular. There is left necessarily a retro-peritoneal cavity of considerable size, the care of which requires attention. This space, though left to itself by many, has given rise not a few times to abscess or septic processes. Bricchetti, in experimenting on animals, urges the necessity of draining this cavity by a tube carried through the skin-wound in the loin. Barwell has also made a similar suggestion, and it seems based on sound surgical principles, but Boothby is the only one who has so far done this with a satisfactory result.*

The conclusion from the broad consideration of the many cases embraced in the paper is, that the important and dangerous operation of nephrectomy can and should be more restricted in its application, and for disease that it will be most satisfactorily employed in suppurative processes which have not been relieved by the simpler procedure of nephrotomy.

37 WEST THIRTY-THIRD STREET, NEW YORK.

Dr. Squibb's Apparatus for the Quantitative Estimation of Urea.

This simple contrivance, which was fully described in a late number of the "Ephemeris," has been introduced into London, where it seems to have met with great favor, since the "Lancet" speaks of it as a "boom."

* In the discussion that followed the reading of the paper, Dr. Stimson reported a nephrectomy, done in 1883, by abdominal section for a painful movable kidney, in which the posterior peritoneal opening was closed and a drainage-tube carried from the renal cavity out through the loin. The result was a fatal one.

CYSTOTOMY FOR VESICAL TENESMUS.*

By DR. NICOLAS SAN JUAN, Mexico,

ADJUNCT PROFESSOR OF DESCRIPTIVE ANATOMY, AND PROFESSOR OF ANATOMY, IN THE ESCUELA DE MEDICINA DE MÉXICO; PHYSICIAN TO THE HOSPITAL MORELOS.

IN not a few instances cystotomy is performed with the view of getting rid of the vesical tenesmus which in many cases is unbearable to women suffering from some uterine complaints. This operation is performed under the belief that vesical tenesmus is located in the sphincter of the bladder, and I shall endeavor to prove that this opinion is erroneous, and to show at the same time that vesical tenesmus takes place in the walls of the bladder instead of in its sphincter.

That idea came to my mind when I saw a woman suffering for nine years from a vesico-urethro-vaginal fistula so extensive as to have destroyed the vesico-vaginal septum, and even a portion of the urethra too. During all this time there was always present a very intense tenesmus, although there was no muscular ring in the neck of the bladder. The tenesmus was subdued by means of local treatment of the mucous membrane of the bladder, and I caused it to reappear at my will by irritating only the vesical mucous membrane. I will say, by the way, that, although the fistula remained open in spite of my efforts, the tenesmus never reappeared after the vesical inflammation was over.

Some months afterward I took under my care a young woman affected with a post-partum cystitis that had caused the lining membrane of the bladder and a great portion of the muscular fibers of its neck to be detached. Notwithstanding the absence of the muscular fibers, there was a very severe tenesmus, which at last subsided completely as soon as the sphacelated mucous membrane of the bladder was extracted; the incontinence of urine disappeared after some months.

Another patient, a man, under the care of Dr. Savista, was suffering from a very intense vesical tenesmus, owing to a complaint of his bladder. Dr. Savista performed urethro-cystotomy, believing this tenesmus would be checked by the section of the sphincter, causing it by this means to cease its contractions. The patient felt a little alleviation after the operation, but the tenesmus reappeared a week later, before the sphincter could have been able to contract again, as the incision remained unhealed, and he was enabled to bring about complete recovery only by local treatment of the mucous membrane of the bladder through the canal of the urethra.

Dr. Siceaga attended a man who was suffering from a very severe tenesmus. After the expulsion of a myxoma and a small calculus the patient improved, but the tenesmus came on again some days later with the same intensity. Urethro-cystotomy was resorted to for extracting some calculi, and the vesical sphincter was divided completely; but it was of no avail, as the patient died twenty-four hours afterward, having suffered constantly with the same tenesmus.

I believe these clinical facts not to be numerous enough to solve the question at once, but I will call your attention to these facts: 1. That in the first case *there was no muscular ring in the neck of the bladder*, and, nevertheless, the tenesmus existed and was subdued by improving the condition of the vesical mucous membrane. 2. That in the second patient the tenesmus *was coincident with the absence of the muscular fibers of the neck of the bladder*, and disappeared by removing the irritation of the same bladder. 3. That in the third case the urethro-cystotomy proved unsuccessful, the tenesmus having been controlled only by local treatment of the vesical mucous membrane. 4. And, finally, that in the fourth patient no alleviation at all was obtained by disabling the sphincter from contracting.

Furthermore, the physiologist, Dr. Küss, in his "Treatise on Physiology," expresses himself in such terms, when on the subject of micturition, as to support my opinions. The paragraphs of his book to which I allude read as follows:

The muscles of the vesical walls bear non-striated fibers, and, consequently, their contractions are sluggish; but at the same time they are also very elastic, so that the bladder is very dilatable, and a great quantity of urine may be accumulated therein. When the distension of this receptacle reaches the extreme it becomes a cause of irritation to the muscular fibers, which then contract, and the bladder tends to expel its contents. We shall see presently that it is the reaction of the bladder against its contents that gives rise to the necessity to urinate. When the bladder is laboring under an inflammation its muscular walls become less elastic and react more quickly upon the contents of the receptacle; hence the frequent desire to empty the bladder under these circumstances.

How the bladder when at rest may retain the urine and prevent its escaping through the orifice of its neck is an important and commonly misappreciated question. It is usually said that the neck of the bladder is closed by the contraction of the vesical sphincter surrounding it; but its muscular fasciculi are very slightly marked, and we know, besides, that a muscle can not be permanently in a state of contraction. The neck of the bladder is always closed, because that is the natural form, the normal condition of its sphincter, like that of all kindred muscular rings; they obliterate when at rest, owing to their own elasticity alone, the orifice they are circumscribing. But when any cause, no matter how slight it may be, acts so as to oppose the action of the sphincter, it becomes unable to intercept the passage, and the urine forces its way through it. Females possess but this apparatus of retention, so that a slight effort, a burst of laughter, causes the emission of a few drops of urine. But very special and powerful arrangements are to be noted in males, which practically make the orifice non-existent when the bladder is at rest. First, the axis of the bladder is far from being vertical; it is rather horizontal. As this organ rests upon the symphysis pubis, which is itself horizontal, the excretory duct, the canal of the urethra, is first directed vertically downward, and then proceeds directly forward, the result being a great tendency in this duct to be compressed when the bladder becomes too full. Then comes the pressure of the prostate, a hard organ composed of fibrous tissue, of glands, and of muscular elements. This prostate is traversed by the urethra, and surrounds it in such a way as to obliterate it completely and to bring its opposite walls in contact. This is in male the principal cause of the retention of urine in the bladder when the organ is at rest. Let the prostate be hypertrophied, and then it will constitute

* An extract from a paper read before the Academy of Medicine of Mexico, July 24, 1884. Translated from the author's manuscript by Dr. Ignacio Alvarado.

an obstacle more and more efficacious, even too efficacious, and, on account of this circumstance, it becomes, in aged persons, the cause of the greatest number of pathological retentions—that is to say, of those retentions which the expulsive efforts of the bladder can not overcome. The flattening of the canal of the urethra and the contact of its walls are affected also by the arrangement of the perineal aponeurosis, the fibrous elastic fasciuli of which pull its walls on each side, being attached to the ascending ramus of ischium and to the descending ramus of the pubes, so that the canal is reduced to a transverse cleft at this level, and a certain effort is required to enlarge its lumen. Thus, when urine is not impelled toward the canal of the urethra, toward the vesical orifice, with a certain force, this orifice does not really exist, and it is no wonder that the liquid may accumulate in the bladder, the muscular walls of which are so elastic and so distable. There is, therefore, no contraction, no physiological act, properly so called, that may intervene to prevent the urine from running out; all the conditions are mechanical ones, and they persist after death, for urine is still present in the bladder of a corpse.

It is not to be said that muscular contractions may not intervene to oppose the passage of the urine; on the contrary, there is a muscle intended for this purpose, but it is not placed on the neck of the bladder, but farther out, on the membranous portion of the urethra; this is the *urethral sphincter*, Wilson's muscle, and its contraction is brought about either by a reflex action or by the influence of the will. The following are the circumstances under which it takes place: When the vesical walls have become too dilated by urine, as we have seen already, they react and compress their contents, which then overcome the elasticity of the neck as well as the elasticity of the prostate, and penetrate into the beginning of the canal of the urethra; there the urine comes in contact with a very sensitive mucous membrane, the *prostatic mucosa*, which, as we shall see, presides over a great number of genital reflexes. It is the contact of the urine with this mucous membrane that produces that burning sensation known by the expression "necessity of urinating," and which, like all the sensations of that region, we perceive as taking place in the outer extremity of the canal, in the fossa navicularis. If we pay no attention to this feeling, a reflex will be produced, which is noticeable by a contraction of the urethral sphincter; the urine can not go farther; it is compelled to retreat on account of the contraction of the muscles of the anterior wall of the prostate, and goes back into the bladder, the contractions of which have then disappeared.

The co-ordinate contractions producing micturition are under the influence of the spinal cord, and especially of its lumbar region. Budge has endeavored to localize more exactly the center for the innervation of the bladder, and his experiments have led him to locate it on a level with the fourth lumbar vertebra (in dogs and rabbits). Kupressow places this center between the fifth and sixth lumbar vertebrae.

The sensibility of the prostatic mucous membrane is therefore very important, since it is the starting-point of this essential reflex; the loss of the said sensibility becomes the cause of that sort of nocturnal incontinence usually termed *enuresis*. This involuntary emission of urine, as, in other cases, the involuntary discharge of feces, attests the insensibility of the mucous membranes to the contact of the excremental products, and in the present case the absence of the premonitory feeling of the necessity of emptying the bladder.

The distension of the bladder going on, it reacts again a few instants afterward, the urine penetrates again into the prostatic region, where it provokes again the same reflex, and so on. This explains the intermittent form presented by the necessity of emptying the bladder. Should these phenomena be repeated,

the reflex would be lessened, and the intervention of the will would be necessary to contract the urethral sphincter and prevent the urine from running throughout the canal; hence the painful character of efforts to resist for a long time the necessity of urinating. It is to be seen, then, that, whenever the obstacle opposed to the passage of the urine is really active, it does not lie in the vesical sphincter, but in the urethral muscle, the only striated and voluntary muscle that antagonizes the contractions of the bladder. We shall see hereafter that this muscle plays also a principal part in one of the mechanical phenomena of the genital apparatus—the *ejaculation*.

But, in general, we obey the first warning that the urethral mucous membrane gives us when we feel the first desire of urinating; this sensation seems to be situated in the *fossa navicularis*, but it really exists in the prostatic mucous membrane. The introduction of a probe into the canal gives rise to a sensation identical with that experienced when there is a need of urinating, as soon as its extremity reaches the mucous membrane of the prostate; and, if we feel this sensation to exist in the outer extremity of the urethral canal, it is through the effect of those associated sensations of which we have already shown many instances.

When we yield to the necessity of urinating, the mere impulsion the urine receives from the vesical muscles would be insufficient to overcome the resistance of the canal and to separate its walls, although there is no obstacle opposed by the sphincter; it requires a slight "effort" of impulsion, by which, under the influence of the muscular contractions of the abdomen, the viscera may press upon the bladder, increasing its action upon its contents. We therefore close the *glottis* at the beginning of micturition, and then the vesical contractions are enough to expel the urine; but a new effort is required when micturition is at its end. The lower part of the bladder is in a fixed condition and has a concave shape, and, consequently, it could not be completely emptied if the abdominal viscera did not press on the upper part of the bladder, compelling this part to descend against the bottom of the bladder so as to completely obliterate its cavity; thus, when the bladder is entirely empty, it has, at least in males—but not in all animals—the shape of an inverted dome, and, in fact, that is the shape found in corpses when the bladder is entirely empty.

Once the bladder is emptied, the urethral canal contracts upon itself and expels its own contents; but if this canal is altered or a previous inflammation has caused it to lose its elasticity, then it does not completely expel the urine, which remains in different parts, contributing, by its contact with the mucous membrane, to maintain its pathological condition.

The statements of Dr. Küss being in entire accordance with the clinical facts already spoken of, I think the following propositions may be deduced therefrom:

1. Both vesical tenesmus and the normal necessity of emptying the bladder take place under the same mechanism, with this difference: that the pathological necessity of emptying the bladder is attended with pain, and oftener felt on account of some special conditions of the urine and of the mucous membrane.

2. Tenesmus sets in as soon as an existing cause acts upon any part of the urethro-vesical membrane when this is in a pathological condition.

3. When there is tenesmus, the contractions take place in the body of the bladder instead of in its neck; and the same, I assume, may be applied to every cavity closed by a sphincter, as all the muscular rings are ruled by the same laws.

4. Urethro-cystotomy is available against vesical tenesmus, because the muscular fibers of the bladder do not need to display so great an effort as in the physiological state to cause the urine to run out, as there is no resistance to overcome in the flow through the fistula; and at the same time because it improves by itself the condition of the mucous membrane, and affords more facilities for restoring its physiological state.

THE PREPARATION OF COCAINE.

By A. CASTAING, PH. G.

COCAINE is undoubtedly the great object of interest of the moment, and there is not a physician of progressive ideas who is not anxious to test the marvelous effects of the new anæsthetic. The drug trade, taken unawares by the sudden and sustained demand for cocaine of the various brands which are guarantees of genuineness, is unable to keep pace with it, and is therefore compelled to offer a substitute in many cases inferior to the article called for by the doctor's prescription. The natural consequence is that the anticipated effect is not produced, and the wished for and confidently expected local insensibility is not attained. The practitioner is disappointed at his first experiment, his professional pride receives a shock, and in his mind doubt takes the place of the enthusiasm he was at first inspired with. Yet it would be wrong to cast the blame upon cocaine, for the alkaloid, when real and chemically pure, does truly possess the power of producing local anæsthesia, not only on mucous membranes, but also on the whole surface of the epidermis, and, to a certain depth, beneath it.

Considering the difficulties attendant on obtaining the genuine article, we think we shall do well to make known a way, which repeated trials have shown us to be the most effectual, to extract the alkaloid from the *Erythroxylon Coca*. Having observed that cocaine is extremely susceptible of change under the influence of acids, we studied how to exhaust the coca-leaves without using acidulated liquids, and discovered the following method, by which one grain of cocaine can be extracted from four hundred and eighty grains of leaves. To obtain this result, however, it is requisite that the coca-leaves be of good quality—that is, gathered at the right time and place, properly dried (a leaf with brown spots on it, resulting from moisture, has lost all value)—and, above all, not injured by age or by exposure to the air and consequent evaporation.

MODUS OPERANDI.—On one part (by weight) of coca-leaves pour eight parts of boiling water, and let them steep for half an hour in a closed vessel in a water bath. Pour the whole into a percolator, and, when all the liquid part is strained off, continue the exhaustion of the leaves by pouring on them eight parts of alcohol at 85°. Mix the two liquors and precipitate them by means of acetate of lead, draw off with a siphon, and then add sulphate of sodium to remove the salts of lead. Filter and evaporate at a gentle heat until the liquid has attained the consistence of syrup. Treat the whole with water to separate the resinous part, and then precipitate with carbonate of sodium. The precipitate is then to be exhausted by sulphuric ether, and the ethereal solution, after the ether is distilled, is exposed to

the air until every trace of ether has completely disappeared. By this means is obtained a crystallized residue of a brownish yellow and of a disagreeable smell. This is impure cocaine.

The coloring matter is removed by washing once or twice with cold alcohol. The cocaine, thus purified, appears in the form of transparent prisms, without smell, bitter to the taste, soluble in seven hundred parts of cold water, more soluble in alcohol, and entirely soluble in ether. The solution has an alkaline reaction, and, when applied to the tongue, it imparts a bitter taste and a certain insensibility, followed by a slight sensation of cold, recalling the effect of ether spray upon the epidermis.

Heated to 208° F., the cocaine becomes liquid, and, under the influence of cold, it becomes a transparent mass, which gradually assumes a crystalline form. If it be exposed to a degree of heat higher than 208° F., cocaine changes its color and decomposes. It is inflammable, and burns with a brilliant flame, leaving an ash behind it. It forms soluble salts with acids (its hydrochlorate is the best) and all these salts are more bitter than the alkaloid. It is a compound of carbon, hydrogen, nitrogen, and oxygen.

The medical profession is well acquainted with the effects of wines, extracts, and infusions of coca. I trust that what I have written above will show clearly how its action varies in accordance with the amount of cocaine contained by the leaves, and that, in order to obtain the true therapeutic effects of coca, it is absolutely necessary that the cocaine be titrated at a fixed dose in all its preparations.

Book Notices.

The Principles and Practice of Gynecology. By THOMAS ADDIS EMMET, M. D., LL. D., Surgeon to the Woman's Hospital of the State of New York, etc. Third Edition, thoroughly revised, with 150 Illustrations. Philadelphia: Henry C. Lea's Son & Co., 1884. Pp. xxiv-17 to 876, inclusive.

So accustomed have the medical profession become to believe that whatever Dr. Emmet attempts to do will be done well that the mere fact that he has issued a new edition of his book carries with it the promise of a minute and conscientious revision. The reader is prepared by a glance at the preface for many changes, but their importance is fully realized only after a careful comparison of this edition with the previous ones. We are happy to add that the unique features of the work remain for the most part unaltered, that those familiar chapters which seem to bear the special impress of the author's personality have been retained in their old form. There are certain portions of the book to expunge or to change which would be to render it strange even to its oldest friends. We believe that, in its present form, Emmet's *Gynecology* will attract more earnest attention abroad than has hitherto been the case, and that its readers in general will appreciate its magnitude as well as its sterling honesty. We should only be repeating what has many times been written if we were to enter into a discussion of Dr. Emmet's well-known theories with regard to uterine pathology and treatment. Doubtless we should re-echo the opinion of many readers if we questioned the soundness of many of his statements as viewed from a pathological standpoint. His strength lies in his vast clinical experience and in the practical

sagacity with which he applies facts to the elucidation of theories. Here he is inimitable. Dr. Emmet has been and always will be accused of "riding a hobby," but this is a reproach frequently cast against men who hold and express decided opinions. It is a sufficient commentary upon the boldness and originality of an author's teachings when he feels obliged to wait until a third edition of his work before he finds the profession ready to receive the opinions which he has held for many years.

It is impossible, within the narrow limits assigned to us, to give more than a cursory glance at the main features of the book, dwelling more particularly upon the new chapters. By far the most important innovation is that introduced in Chapter XX, which is entitled "prolapse of the posterior wall of the vagina," instead of "laceration of the perineum," as in the former editions. The first impression of the reader who derives his ideas of Dr. Emmet's new teachings entirely from this chapter will doubtless be similar to that which was created at the American Gynecological Society when his original paper upon this subject was presented. One of the gentlemen then present expressed the opinion that the writer had "wiped out all his former teaching." If any one will carefully review Chapter XX in the old editions, he will not only be convinced that Dr. Emmet has never committed himself to the full extent of the theory that regards the perineum as a supporting structure, but he will discover in the carefully worded statements there made that the innovation is not so startling as it would at first sight appear. The point which will strike the reader as most radical is the fact that between "supposed" and real laceration of the perineum the author admits no middle ground. Unless the tear extends through the sphincter, it is practically disregarded. We believe that this theory will prove a stumbling-block to not a few. The author's arguments as to the cause of prolapse of the posterior wall are urged with all his usual earnestness and sense of personal conviction. They require close attention in order to their perfect understanding, but, once having been grasped, they are convincing. Dr. Emmet has dealt a deadly blow to the mechanical theory of the perineal body, but we question if an idea so firmly grounded as this is in the minds of the American profession can be dislodged in a single generation. But, if the explanation of the cause of the condition is not an easy one for the general practitioner to grasp, how much more difficult will be the description of the author's new operation to one who has never been so fortunate as to witness its performance! It is an operation of which it may be said most emphatically that, to be understood, it must be seen and studied. With all deference to Dr. Emmet's forcible description, we must confess that we could not perform the operation from merely reading his account of it, nor does it seem to us that Fig. 67 (p. 375) gives as clear an idea of it as we might wish. Quite different is the admirable figure which follows (68). But we believe that the operation and the theory upon which it rests are both sound, and that they bear the highest testimony to the originality and careful observation of the author. There will be many readers who will be disposed to question the writer's remark, when he compares the present method of procedure with the old one, that the "operation is easier of execution, although the details may render it more tedious."

Important changes will be noted in the paragraphs on laceration through the sphincter. The author's present practice in closing these ruptures may be summarized by quoting his expression that he now treats this condition "as a recto-vaginal fistula situated in the median line." An essential difference will be noted between the present method of after-treatment in these cases and the old one.

The important chapters upon laceration of the cervix bear the marks of careful revision. Without receding from his origi-

nal position, Dr. Emmet meets the objections which have been brought against his operation, and, in our opinion, answers them in a masterly way. No thoughtful reader will accuse him of not being sufficiently conservative here. These pages have been enriched by the introduction of several new and excellent illustrations. It can not be otherwise than gratifying to one who has labored so long and faithfully to establish a principle which he firmly believes to be right to be able to publish such ample and convincing testimony in its favor. Dr. Emmet's teachings long ago ceased to be local. When he speaks now, it is to a listening world, no longer to the few auditors of his clinic. At the recent medical congress at Copenhagen, Martin referred somewhat reproachfully to the fact that Emmet made no mention in his book of diseases of the Fallopian tubes. That reproach can no longer be made, as Chapter XXXVII is devoted to that subject. Doubtless it would have been easy for Dr. Emmet to introduce a chapter on salpingitis into his former editions, but it is well known that he does not accept any statements which he has not verified by long and conscientious study and observation. Consequently, when he writes on a new theme, we may be sure that he has made it his own and in his own way. We may, perhaps, regret that he has not devoted a little more space to a topic which has now such a living interest, and it must be confessed that the pathology is rather limited, but the chapter is a suggestive one, and implies quite as much as it expresses.

The pages on recent methods in abdominal surgery, extirpation of the cancerous uterus, etc., are fully up to the times. So impressed is the author with the necessity of strict antiseptic precautions that he says, in his usual forcible style, that a man who would knowingly be present at an operation after having been exposed just previously to septic influences "is morally as responsible for the death of the patient as if he were to put a bullet through her skull." This is strong language, but the writer is a man who means what he says. We may regard this as an index of the strength of his convictions upon this important subject.

As we turn to the latter part of the volume, which treats of diseases of the bladder and urethra, it is with the feeling that we are now standing upon solid ground. Whatever unguarded points may exist in other portions of his book, here Dr. Emmet is impregnable. It is as impossible to question the results of his work as it is to refrain from admiration at the patience and ingenuity displayed in it. We have always felt that foreign gynecologists had fixed their attention too exclusively upon his labors in behalf of the operation of trachelorrhaphy, and had too often lost sight of his work in the direction of urethroplasty. This is not strange, seeing that the American profession apparently know little of it. It may be that the subject does not possess enough general interest. Whatever the reason of this apathy may be, we trust that one of the effects of the present volume may be to direct attention to it.

The "button-hole operation," as the author denominates his process of establishing an artificial urethro-vaginal fistula, is another important question which is thoroughly discussed in the present edition. We question if the average reader will share the author's enthusiasm as to the efficacy of this measure when adopted for the relief of cellulitis. The exact manner in which this relief is given is not clear. But Dr. Emmet has been very guarded in his statements, and we can not afford to dismiss lightly what he says on this subject. The operation, when performed for the removal of other than urethral or vesical symptoms, is liable to abuse in the hands of those who are less experienced than he in recognizing the exact indications which render it advisable. Few will doubt its usefulness as a preparatory step in the treatment of strictly urethral affections.

As we have before stated, our space does not allow us to dwell upon minor imperfections. Yet we would call attention to the fact that, while many new woodcuts have been introduced, some of the old ones are not quite so distinct as in the former editions. The general arrangement of the subject-matter has been greatly improved, and it is evident that much attention has been given to correcting certain verbal errors that appeared in the old editions. A few of the latter still remain—for instance, on page 765, it seems to us that the author's intention was that the opening sentence of the last paragraph should be the closing sentence of the preceding paragraph. Such a change would materially modify the sense. Again, on page 217, sixteenth line from the bottom, the word "bladder" is printed, where evidently *rectum* was intended.

It is difficult to think of Dr. Emmet's book apart from its author. Every page is the reflection of his honest and kindly heart. But, while it is so intensely personal, there is no display of erudition, no attempt to magnify the individual rather than the work. Perhaps it is this personal element which has always rendered the book such an authority with us. But this is not enough. It should be more carefully studied than has been the case. Its merits do not lie on the surface. The fact that Dr. Emmet's ideas have been so misconstrued, even in New York, is sufficient proof that the magnitude of his work has not been appreciated. We look for a wider and deeper appreciation still, and we prophesy that it will come, if not now, hereafter. It is seldom given to reformers to enjoy the full fruition of their labors, but, if the admiration and respect of hundreds who have never listened to his voice is any reward to a teacher for over a quarter of a century of faithful toil, Dr. Emmet may be said to have been fully repaid.

BOOKS AND PAMPHLETS RECEIVED.

A Manual of Bandaging. Adapted for Self-Instruction. By C. Henri Leonard, A. M., M. D., Professor of the Medical and Surgical Diseases of Women, and Clinical Gynecology, Michigan College of Medicine, etc. With One Hundred and Thirty-nine Engravings. Second Edition, revised and enlarged. Detroit: The Illustrated Medical Journal Co. Pp. 159. [Price, \$1.50.]

Surgical Handicraft. A Manual of Surgical Manipulations, Minor Surgery, and Other Matters connected with the Work of House Surgeons and Surgical Dressers. With Two Hundred and Eight Illustrations on Wood. By Walter Pye, F. R. C. S., Surgeon to St. Mary's Hospital, etc. Philadelphia: P. Blakiston, Son & Co., 1884. Pp. xx-544. [Price, \$5.]

A Text-Book of Hygiene. A Comprehensive Treatise on the Principles and Practice of Preventive Medicine from an American Standpoint. By George H. Rohé, M. D., Professor of Hygiene, College of Physicians and Surgeons, Baltimore, etc. Baltimore: Thomas & Evans, 1885. Pp. ix-324.

The Law and Medical Men. By R. Vashon Rogers, Jr., of Osgoode Hall, Barrister-at-Law. Toronto and Edinburgh: Carswell & Co., 1884. Pp. xiv-214.

FRANK F. FOSTER, M. D.

NEW YORK, SATURDAY, DECEMBER 27, 1884.

THE REPORT OF THE SURGEON-GENERAL OF THE ARMY.

THE condensed nature of the last annual report of the Surgeon-General of the army renders it anything but light reading; the fifty-eight pages comprised in it represent an immense amount of patient and accurate work. It appears that the whole number of deaths was two hundred and seventy-two, seventy-nine of which were due to injuries. Some interesting statistics are given, embodying a comparison between the health of the white troops and that of the colored troops. There were four times as many deaths from diseases of the respiratory organs among the latter as among the former. There were two hundred and twenty-two cases of typhoid fever in the army during the year, thirty-eight of which proved fatal. Attention is called to the fact that this is double the highest rate of prevalence recorded in any other year since the war; but, to offset this, the mortality has been reduced from twenty-one to sixteen per cent. Some valuable statements are furnished as to the causes of the occurrence of the disease at different stations, Jefferson Barracks, Mo., being regarded as the starting-point of the infection. Only one case of yellow fever was reported from the entire army.

The report shows that the Army Medical Museum has been enriched by a number of new specimens, so that the whole collection now includes 23,141; and that the Library of the Surgeon-General's Office has been increased by the addition of four thousand volumes and fifty-five hundred pamphlets, making the total numbers now 65,738 volumes and 86,503 pamphlets. It is stated that the number of persons making use of the library has shown a decided increase, and that every effort is being made to render the collection exhaustive. Obituary notices of Surgeon-General Crane, Surgeon Cuyler, and Surgeon Woodward are included in the report. The pamphlet closes with several statistical tables, evidently compiled with the care and accuracy that characterize the work done by the medical corps. We can not over-estimate the importance of such statistics as these, gathered as they are by a number of intelligent and thoroughly educated observers, who combine [with their medical acquirements the habits of rapid decision and prompt execution learned in their military discipline. There is always a unity, together with clearness and brevity, about the medical reports of the army that renders them specially valuable for reference. We heartily congratulate Dr. Murray upon his first annual report as Surgeon-General.

NEWS ITEMS, ETC.

Infectious Diseases in New York.—We are indebted to the Sanitary Bureau of the Health Department for the following

statement of cases and deaths reported during the two weeks ending December 23, 1884:

DISEASES.	Week ending Dec. 16.		Week ending Dec. 23.	
	Cases.	Deaths.	Cases.	Deaths.
Typhoid Fever.....	32	7	19	5
Scarlet Fever.....	101	21	92	20
Cerebro-spinal meningitis....	5	3	6	7
Measles.....	147	19	103	23
Diphtheria.....	76	32	62	28

The Death of Professor Carl Vierordt, of Tübingen, is reported in the "St. Petersburg medicinische Wochenschrift" as having taken place on the 22d of November, in the sixty-seventh year of his age, after a lingering illness.

The Death of Professor von Wittich, of Königsberg, is announced in the "Lancet."

Army Intelligence.—*Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 14, 1884, to December 20, 1884:*

LAUDERDALE, JOHN V., Captain and Assistant Surgeon. (Fort Sully, Dakota Territory.) Granted leave of absence for one month, to take effect about December 20, 1884. S. O. 146, Department of Dakota, December 9, 1884.

COMEGYS, E. T., Captain and Assistant Surgeon. Granted leave of absence for one month. S. O. 234, Department of the Missouri, December 8, 1884.

PILCHER, J. E., First Lieutenant and Assistant Surgeon. Ordered to Fort Custer, Montana Territory, for duty. Order assigning him to duty at Fort A. Lincoln, Dakota Territory, amended. S. O. 144, Department of Dakota, December 8, 1884.

Naval Intelligence.—*Official List of Changes in the Medical Corps of the United States Navy for the week ending December 20, 1884:*

KINDLEBERGER, D., Medical Inspector. Detached from the Hartford, and placed on sick leave.

Society Meetings for the Coming Week:

TUESDAY, December 30th: Boston Society of Medical Sciences (private).

WEDNESDAY, December 31st: Auburn, N. Y., City Medical Association; Berkshire District, Mass., Medical Society (Pittsfield); Cumberland County, Me., Medical Society (Portland).

SATURDAY, January 3d: Clinical Society of the New York Post-Graduate Medical School and Hospital; Miller's River, Mass., Medical Society.

Letters to the Editor.

A CARD FROM DR. FORDYCE BARKER.

To the Editor of the New York Medical Journal:

SIR: Will you allow me a little space to express the deep feeling of my heart at the reception of a great number of letters since last Friday morning? As, from the medical profession of this city and Brooklyn, I have already received more than two hundred, and very many letters and numerous telegrams from other places, it is quite impossible for me to send an acknowledgment to each writer, I must pray my friends to accept my thanks through the medium of your journal.

FORDYCE BARKER.

MONDAY EVENING, December 22, 1884.

Proceedings of Societies.

NEW YORK SURGICAL SOCIETY.

Meeting of December 9, 1884.

The President, Dr. ROBERT F. WEIR, in the chair.

Imperforate Anus; Fistulous Communication between the Rectum and Vagina.—Dr. C. K. BRIDDON presented a child two years old, which he saw for the first time Saturday last, at the Presbyterian Hospital. The mother stated that it had retention of urine, for which the catheter was used twenty-four hours before, but that since the catheterism no urine had passed. She further stated that the fæces came from the "front passage," and that sometimes the urine was clear and sometimes it was foul with fæces. On examination, it was found that the child's belly was enormously distended, that the distension belonged to the alimentary canal, and was particularly marked at the sides of the abdomen, but especially on the left side, where a hard tumor could be felt distinctly. Dr. Briddon introduced a catheter into the bladder, and about eight ounces of perfectly clear urine were withdrawn. While the catheter was tightly compressed by the urethra, an instrument sufficiently large being used to fill it to distension, a small quantity of fecal matter passed from the vagina, and, on inspection, it was found to come from a fistulous communication with the rectum.

His impression then was that it was a case sufficiently urgent to demand immediately the operation of inguinal colotomy, but without trouble he introduced an elastic catheter into the intestine through the vagina, and then pumped in warm water, and allowed it to return, bringing away fluid fæces. The injection of the intestine was continued for about an hour and a half, and during this time friction of the belly was made with vaseline. At the end of that time the alimentary canal was apparently entirely empty. The child was then sent home with the direction to return on the following Monday, when the injections were repeated. It was well known that fistulous communication between the rectum and bladder might go on without giving rise to much trouble during infantile life, but, as soon as the stools become formed, intestinal obstruction was likely to occur, which would call for interference of some kind. Dr. Briddon found that he could pass the sound readily upward in the alimentary canal so that it could be felt through the integument in the left inguinal region. Withdrawing the sound a trifle and reversing it, he could then feel the end of the instrument just in front of the point of the coccyx. He contemplated either making an incision where the natural opening should be, removing as much of the coccyx as might be necessary, and then dissecting up to the intestine, making an opening in it, and stitching its edges to the skin, leaving the recto-vaginal fistula for after-treatment in adult life; or performing Rizzioletti's much more complete operation, which consisted in making an incision in the median line of the fourchette as far back as necessary, separating the entire wall of the rectum, bringing it down, and placing it behind the normal position in this particular instance, as was rendered necessary by the position of the ischia. After the rectum was attached to the integument immediately in front of the coccyx, the vaginal wound was to be stitched from within, and a perineum formed by coaptation of the sides. In six of the cases reported in Curling's work on the rectum the results had been very good in after-life.

Dr. J. L. LITTLE has seen this child when it was about three weeks old. He made the same examination which Dr. Briddon had made, and could verify the existence of a fistulous communication between the rectum and the vagina. At that time he hesitated to operate because of the delicate condition of the

child. His idea was to operate according to the method mentioned by Dr. Briddon, and afterward to close the recto-vaginal fistula.

Dr. HENRY B. SANDS had also seen this child, and advised that nothing be done until it reached a more mature age.

The PRESIDENT said that fifteen years ago he had a case of this kind, in which he performed a similar operation. The patient reached the age of four years, and then died of some intercurrent affection.

Dr. BRIDDON remarked that it was difficult to separate the entire walls of the rectum and bring it down, but he thought it worth the trouble to try to perform the operation.

Dr. ALFRED C. POST referred to a case of absence of the rectum in which he was obliged to bring down the intestine from a height of two or three inches and attach it to an opening in the integument. It did very well for some time, but contraction occurred from neglect on the part of the parents, and afterward he was obliged to dilate the part with tents of soap, and the child had subsequently had free evacuations, and had enjoyed good health.

Excision of the Elbow.—Dr. CHARLES MCBURNEY presented a girl, nineteen years old, upon whom he performed excision of the elbow eighteen months ago for osteitis, which originated in traumatism received two years before the operation. The forearm was flexed at an angle considerably less than a right angle, and the entire arm was quite useless from pain and immobility. The operation was performed by making a long posterior incision, and removing the entire head of the radius, the articular end of the ulna, and one inch of the lower end of the humerus. The patient had now good use of the forearm, and played considerably upon the piano, being able to play for an hour at a time. Flexion and extension and pronation and supination were very good. The patient also had morbus coxarius, for which she was being treated by the use of a mechanical appliance. The operation was performed on the 8th of May, and on the 9th of July the patient was able to perform the present amount of flexion and extension.

Dr. BRIDDON referred to a case in which supuration of the elbow joint continued for seven or eight months, and the sinuses were eventually healed by the injection of a stimulating solution, but it was supposed that the limb was useless. The finger and thumb could be inserted between the extremities of the bones. To aid the patient in using the arm, Dr. Briddon had constructed a tin angular splint, which enabled her to discharge her household duties with considerable facility. Occasionally the angular splint would get out of order, and on one of these occasions, while it was away to be repaired, the patient found that she could use the arm as well as before the operation. From that time the splint was discarded, and she continued to do her household work with a joint which in scope of movement did not compare with that in the case presented by Dr. McBurney.

Wryneck, with Paralysis of the Serrati Muscles.—Dr. A. G. GERSTER presented a patient, a boy, who exhibited wry-neck and a peculiar position of the right shoulder-blade, namely, that characteristic of paralysis of the serratus muscle. The essentials of the history were, that the child, some time before it was one year of age, suffered from whooping-cough. Ever since that time this peculiar position of the head had been noticed. Nothing was noticed concerning the scapula at that time. When the patient was examined superficially, the first point which attracted attention was a peculiar elevation corresponding to the course of the upper border of the trapezius muscle, which made it appear as though contraction of this muscle was present. Indeed, that diagnosis was made by several of Dr. Gerster's colleagues. The position of the scapula, however,

was such that the assumption that it was due to the contraction of the trapezius muscle could not explain it. The contraction of the trapezius which was present would go far to explain the wryneck. In order to fairly explain the causation of the malposition of the scapula, Dr. Gerster anesthetized the patient, and found that the scapula, when the muscle was flabby, did not reach the normal position, as it should have done if the malposition was caused by the contraction of the trapezius alone. Further, when contraction of the trapezius was induced by the faradaic current, the malposition of the scapula was not influenced, and it was evident that the malposition was due to the contraction of the levator scapulae and the rhomboid muscles. He also tested the reaction of both serrati muscles, and found that the normal power of these muscles was not present on the right side, as could be easily illustrated by irritation of the muscles on the left side. Contractions of the serrati muscles on the side of the lesion could be elicited, but they were insufficient to bring the scapula into its normal position.

The scapula was drawn upward and inward toward the spine, and at the same time the inner border of the bone was not in contact with the thorax, but elevated from it, or more prominent than normal. At the same time the entire scapula was rotated about its antero-posterior axis. An apparent tuberosity, corresponding to the upper and inner angle of the scapula, was produced by the upper internal angle of the scapula itself, and not by the contraction of the muscles.

His explanation of the condition was, therefore, that it must have originally been a case of infantile paralysis of the serrati muscles of the right side, and that the contraction of their antagonists and the rhomboids took place then, and out of this contracture was finally evolved which remained permanently. It was a rare malposition, and therefore he presented the case. It was a question whether dividing the contracted muscles would help to correct the malposition. The circumference of the thorax had been measured, and it was ascertained that the affected side was smaller than the other, both in inspiration and in expiration—smaller during expiration by half an inch.

Extirpation of the Kidney.—The PRESIDENT then read a paper on this subject. [See page 721.]

Dr. W. S. HALSTED thought that, irrespective of the question of comparative risk, most would allow that neoplasms of the kidney could be more satisfactorily dealt with through the abdominal incision. Certain operators, who were complete masters of the technique of abdominal surgery, would be justified in preferring and practicing laparotomy in the removal of kidney tumors, whereas the great majority of surgeons might prefer, for the present, to confine themselves to the lumbar incision. Each surgeon should, therefore, be the conscientious judge of his own attitude. Thus it was easy to comprehend why von Bergmann, Thornton, Tait, and others should adopt the abdominal incision; and, although Tait would not confess the secret of his success, it was quite apparent to others that it was to be ascribed to operative skill and most careful asepticism.

Dr. Halsted was inclined to advocate, for the abdominal incision, a line lateral to that recommended by Langenbuch, for two reasons: first, to avoid, if possible, subsequent hernia, and second, to enable one, early in the operation, to sew off the operation-field from the general peritoneal cavity. It seemed to him that the suggestion from Hagen Torn ("Centrabl. für Chir.," No. 35, 1884) to cut through the rectus abdominis muscle rather than through the linea alba, to prevent hernia after ovariectomy, was a good one. He advised also that especial attention should be paid to the sewing of the incision through the oblique and transverse abdominal muscles. A cross-cut of such a wound would give two lines, irregularly concavo-convex, demonstrating that the various tissues had retracted unequally,

and that, to make the cut surfaces offer the broadest possible face, it would be necessary to convert the undulating into plane surfaces. This could be done by one or more rows of buried sutures aimed at the concavities. To enable one to operate outside of the peritoneal cavity, Dr. Halsted recommended a procedure to which he had resorted in his case. The abdominal cavity was opened along Langenbuch's line. In future cases he would open it outside of this line, as just described. In front of the carcinomatous kidney was the descending colon. The parietal peritoneum was a second time divided at about three inches from the outer border of the colon and the kidney readily removed. The hemorrhage from the kidney-bed was rather profuse from, perhaps, about a hundred oozing points. This was only partially controlled by about as many catgut ligatures. The peritoneal cavity was then closed off from the field of operation by uniting the mesial edges of the twice-divided peritoneum. Thus an extra-peritoneal cavity was formed, bounded postero-externally by the kidney-bed and the abdominal paries which had been robbed of its peritoneum; antero-externally by the isolated strip of peritoneum, the margins of which were the lateral edges of the original parietal incisions; and internally by the outer surface of the somewhat curtailed peritoneal cavity. The extra-peritoneal cavity was drained (anteriorly) by two large rubber tubes. The hemorrhage stopped at once from intestinal pressure and convinced the operator that he might have spared himself much trouble and the patient some shock, if, instead of applying so many ligatures, he had earlier closed off the peritoneal cavity as described. The patient recovered rapidly from the shock of the operation and passed a comfortable night. In the morning he developed uræmic convulsions, which recurred at intervals until his death, about twenty-seven hours after the operation. He secreted, in this time, only an ounce and a half of urine.

A complete autopsy was not allowed. Injection of the extra-peritoneal cavity demonstrated that the peritoneal cavity had been completely shut off. In the latter was about a drachm of slightly stained serum, but there were no other evidences of peritonitis. Microscopical examination revealed advanced interstitial disease of the right kidney. Dr. Halsted thought it fair to attribute the convulsions to the condition of the right kidney, for the patient's pulse was too strong to make it probable that diminished blood-pressure alone might have been the cause of the oligouræsia.

(To be concluded.)

NEW YORK COUNTY MEDICAL ASSOCIATION.

Meeting of December 15, 1884.

The President, Dr. WILLIAM DETMOLD, in the chair.

Discussion on Asiatic Cholera.—Dr. E. G. JANEWAY opened the discussion. He answered the practical questions connected with the subject as they were put at the cholera conference of the Berlin Health Office recently: 1. Whether cholera was produced by a specific infectious agent coming from India. Dr. Janeway thought almost all scientific men at the present time would answer this question in the affirmative. 2. Was the infectious matter only spread through human intercourse? 3. What were the carriers to distant countries—whether ships, goods, letters, sound men, or men sick with cholera? It had been shown beyond doubt that the cholera poison could be carried by certain forms of merchandise. 4. What were the carriers of the infectious matter in near neighborhoods—whether corpses, infected articles, such as food, wearing apparel, water for cooking or for domestic purposes, the air, or insects? It was difficult to give a positive answer to the questions embodied in the fourth interrogatory. It would seem that, at least under

certain circumstances, the body of a person who had recently died of cholera might contain a considerable number of the comma bacilli, which, coming in contact with the clothing, might spread the disease. It was perfectly reasonable to suppose that water for drinking and domestic purposes might afford very favorable means for carrying the cholera germ, but it had been proved by Koch that, so far as the comma bacillus was concerned, it could not live in perfectly clear water; there must be a certain amount of impurity in the water to encourage its growth.

5. Was it necessary for the cholera dejecta to undergo a change in the ground before they could become infectious? There could be little doubt that external surroundings might favor the spread of the disease, but that any such change in the dejecta was necessary to the development of the disease was another question. Certain facts went to prove that the dejecta might be infectious without undergoing any decomposing change after leaving the body. The fact that certain persons had swallowed the dejecta of cholera patients, and had not afterward acquired cholera, proved nothing definite except that such persons were not susceptible to cholera at that time.

6. Was the infectious matter contained alone in the dejecta, or in them and the vomited matter, or did it also exist in the urine, the breath, the perspiration, and the blood? Many persons believed that it existed alone in the dejecta. For practical purposes, it was better to treat each case as if both the vomited matter and the dejecta were capable of carrying the infectious matter.

7. Did the infectious matter possess great resisting power? Clinical observation justified us in answering in the negative, and Koch's experiments had proved that the comma bacillus did not possess great resisting power. We had had cholera in New York several times, and it had always died out in a comparatively short period.

8. Was the infectious germ killed in a short time by drying? This question, so far as the comma bacillus was concerned, could be answered in the affirmative; this germ would not outlive a day of drying, and usually not over three hours.

9. Did the infectious matter find entrance into the system through other channels than the digestive tract? This was an important question which should be positively settled, and yet it was very difficult to say whether the poison of cholera could be inhaled into the lungs and thus indirectly reach the alimentary canal, or whether it always gained entrance by being swallowed with the saliva, with the food, or with impure water.

10. Were special individual dispositions necessary for the poison to be active? This interrogatory all knew should be answered in the affirmative with regard to cholera as with regard to all other infectious diseases. He knew of no more marked illustration of the influence of individual predisposition in the contraction of contagious diseases than that of the case of Dr. Mott, of the Riverside Hospital. Dr. Mott had charge for a year of five hundred case of typhus, and did not himself contract the disease. The next year he had charge of a group of patients, twenty-three per cent. of whom died of typhus, and yet he escaped having the disease. He again had charge of about twenty patients, only one of whom died, and from this group he himself contracted the disease, and it proved fatal.

11. How long was the period of incubation? It had been said, at the Cholera Conference in Berlin, that the period of incubation was not less than two days, and not more than five.

12. Did one attack of cholera give immunity from future attacks?

13. Was the infectious agent of cholera the comma bacillus? The reasons for answering this in the affirmative had been plainly set forth by Professor Flint, in his paper recently read

before the society. But at that time Koch had not yet been able to show that the comma bacillus, when introduced into the alimentary canal of the lower animals, would cause cholera; since then, however, he had been able to demonstrate that fact, supporting previous observations made by other gentlemen, and this, as it were, constituted the missing link in the proof that the active agent in the production of Asiatic cholera was the comma bacillus.

In view of the fact that cholera was extremely likely to be brought into the United States next spring or summer, certain questions with regard to sanitary measures should at this time be well considered.

With regard to quarantine (which, however, was a subordinate question), should it be maintained or not? While it had not prevented the bringing of cholera to this port in the past, it might, if properly carried out, do so in the future. It was specially desirable in cases in which the boxes of immigrants coming from a cholera-infected port had not been opened on the way. A very important question was, What measures should be taken for putting New York city in a condition to prevent the spread of cholera if it was imported? There were many conditions in the city which, if corrected before cholera broke out, would in a great measure tend to prevent the spread of the disease. There were some things which should be done during the winter, because, if not done until cholera reached the port, they would be done in a hurry and at a disadvantage. To begin with, few of us realized how many privy vaults were in use in the city which were not connected with the sewers, and still fewer persons understood the reasons why such privy vaults were in existence. The reasons were, that certain judges of the law maintained that a privy vault was not a nuisance unless it made a stink in the locality at the time of the pending of the suit. It seemed to the speaker that these privies ought during the winter to be cleaned and disinfected, and, if necessary, more than once. It would be a great advantage to the city, notwithstanding the hardships which it might cause individual property-owners, to substitute for such vaults what were called trough closets. It was also important that the Board of Health have sufficient money to keep incessant watch in all doubtful cases of diarrhoea. It was not sufficient that a sum of money be appropriated to be used in case the cholera should appear, but a certain amount should be devoted to defraying expenses incurred in investigating during the spring all cases of disease of a suspicious character. It would also be well to place a sufficient sum of money at the disposal of the Health Board, enabling them to prepare places in the different wards where persons taken down with cholera could be immediately transferred, without the necessity of transportation to a distant hospital, for in many instances patients would die of the disease before they could be taken to a hospital.

Another means for the prevention of the spread of cholera was to carry the sewers out to the end of the piers, thus getting rid of the foul odors which existed in many of the slips along the river-front. It was not certain that the water in the rivers contained a sufficient amount of salt to destroy all the comma bacilli if they were not swept out into the current.

The number of deaths from cholera in this city in 1832 was, in round numbers, 3,500; in 1834, 900; in 1849, 5,000; in 1852, 3,000; in 1854, 2,900; and in 1866, 1,100. There were, then, fewer deaths from cholera in 1866 than in 1832, notwithstanding the large increase in population. He thought that the measures taken against the spread of cholera in 1866 had saved the city many lives. This pointed to the importance of again adopting efficient means of prevention. What were the best means of disinfection? Should we use agents which would arrest the growth of the germ, but which Koch would consider as entirely

unnecessary because supererogatory? Should we trust to the drying process alone, or should we also fumigate? It would be wiser to resort to other disinfectants also, as well as to drying, although it might prove superfluous, and especially it would be of advantage to fumigate houses with sulphur, as we should then be certain that they would afterward be thoroughly ventilated, whereas, if no disagreeable odor was present, it would be difficult to induce the people to permit of thorough ventilation where cholera had existed.

Should the streets be kept dry, or should the gutters be flooded with clean water, or a disinfecting solution? What disinfectants should be used? What discharges should be disinfected? Simply the dejecta of cholera patients, or the discharges in all cases of diarrhoea and dysentery during a cholera epidemic? The speaker believed that cholera had often been spread from patients who had been regarded as having a simple diarrhoea. How should cases of cholera morbus be treated in years when cholera was expected to make its appearance? He had known families to be subjected to a great deal of fear, inconvenience, and expense because one of the members suffering from cholera morbus was said by the physician to have cholera. Here the question would arise, and had arisen in the Cholera Conference before the Berlin Health Office, Should we trust to a diagnosis of cholera based upon the presence of the comma bacillus? He agreed with Koch, who, in reply to a question, said it would be better to treat a case of cholera morbus as if it were one of cholera if it occurred in a place which was in the neighborhood of a cholera epidemic, notwithstanding the fact that the comma bacillus could not be found in the dejecta. With regard to distinguishing the comma bacillus, Koch said we should not trust alone to examination of the dejecta, but resort to culture media.

The following were some of the agents which Koch had found would prevent the development of the comma bacillus: A temperature below 16° C. Freezing did not kill, but only prevented the growth of the germ. A temperature of 100° C. killed the bacillus. A saturated solution of iodine prevented its growth; also, a ten-per-cent. dilution of alcohol; sulphate of lime, two-per-cent.; alum, one-per-cent.; camphor, one part in three hundred; carbolic acid, one in four hundred; oil of peppermint, one in two thousand; sulphate of copper, one in twenty-five hundred; quinine, one in five thousand; bichloride of mercury, one in one hundred thousand. Drying over an hour, or at most over twenty-four hours, killed the bacillus. As to whether all the agents which prevented its growth also destroyed it, Koch was not prepared to say.

Dr. Janeway said he had not much to offer with regard to the treatment, but would call attention to the recent suggestion to inject large quantities of a saline solution under the skin. In addition to a solution of common salt, bicarbonate of sodium and some other alkalis had been suggested.

The President thought the march which cholera had always taken was by commerce from India to other countries. The question of its being due to a microbe was not, in his opinion, definitely settled. As he had made no experiments or observations in this direction, he could only express an opinion, but we knew that there had been fashions in medicine. That certain secretions would favor the development of certain micro-organisms he had no doubt, but at what time during the gradual development of the disease these organisms made their appearance it was difficult to say. He could remember very well when a very intelligent young man, who had studied in Europe, came to this country and undertook to demonstrate to the medical profession the presence of a cancer cell, but that view had long since been exploded, and we all knew very well that there was no such thing as a cancer cell in the sense in which

that gentleman spoke of it. Then some physician pretended to have discovered a bacterium which was the cause of syphilis, and this again was soon abandoned.

Dr. Austin Flint, Sr., had seen more or less of cholera during every epidemic which had prevailed in this country. In 1832 he was a student, and saw some cases. In 1849 he was practicing in Buffalo, where there were over twenty-five hundred cases and eight hundred deaths. He treated some hundreds of cases in hospital practice. He had recorded the histories of about a hundred, and quoted from those histories in illustration of certain points in the discussion. When he was the editor of a medical journal he expressed the opinion, founded on a study of the epidemic as it appeared in Buffalo in 1849, that the disease could not have been spread from one person to another or by means of a contagious principle. However, irrespective of the question whether or not the specific cause of cholera had been discovered, he had since been led to believe that the opinion expressed in that article was incorrect; he now believed that cholera was a communicable disease. One question had presented itself to him as one of practical moment, namely, whether the cases of apparently ordinary diarrhoea which occurred in considerable numbers during a cholera epidemic were due to the presence of the special cause of cholera. Quoting from his former writings, Dr. Flint said: "Anterior to the appearance of the disease in this city, and during the whole period of its continuance, disorders of the digestive system were extremely common. The proportion of the population that entirely escaped these disorders was small. The disorders consisted in diarrhoea or looseness of the bowels, preceded and accompanied by nausea, griping pains, etc." These symptoms, which could be speedily arrested by treatment, would return again and again as soon as remedial measures were neglected. The patients were longer in recovering their strength than after an ordinary diarrhoea occurring when no epidemic of cholera was present. If in these cases the microbe which was the cause of cholera was present, it would go far toward explaining the rapid spread of the disease. Yet it was not easy to explain the exemption of hospital physicians and nurses from cholera. In one of the hospitals for cholera patients not a single attendant, nurse, or physician contracted the disease.

Dr. Flint then directed attention to the prevention of cholera by the treatment of the premonitory diarrhoeal symptoms. This certainly would be a very important matter in case an epidemic should break out. He was satisfied that the disease was diverted in many of the cases in which the premonitory symptoms were treated during the epidemic in Buffalo. The treatment should be by absolute rest and opiates. But the diarrhoea at first was of such a mild nature that it was almost impossible to induce the people to regard it as the precursor of cholera, and to treat it accordingly. For this reason he thought it an important sanitary precaution to establish a system of house-to-house visitation, having a physician look in upon every family in the city once or twice a day during a time of cholera, and inquire whether there were any cases of simple diarrhoea in the house. The persons making these observations should be provided with simple measures, accompanied by directions how to use them, which should be left with the family.

Dr. S. S. Purple had had experience in the epidemic of cholera in New York city in 1849, and related the history of the outbreak of the disease. It was first brought to port the second or third of December, 1848, and afterward cases occurred in the Five Points, rapidly increasing in number. The Five Points at that time was in an exceedingly foul condition, and the disease spread from what was known as "Hug-pen Alley." The history of that epidemic showed very clearly the necessity of cleaning any foul places that might now exist in the city.

Dr. JOHN DWYER had had charge of about three hundred cases of cholera during the epidemic of 1866, and about half of them proved fatal. He made post-mortem examinations in twenty-four cases, and the only peculiar condition which fixed his attention was the fact that in nearly all the cases the gall-bladder was quite full of bile. He was unable to give any explanation of the phenomenon. Dr. JANEWAY had stated that the epidemic on Blackwell's Island had not been traced to any particular case. Dr. Dwyer said it was introduced into the hospitals on Ward's Island by a woman named McCoy, and a fact opposed to the length of the period of incubation, which Dr. Janeway had cited as being not less than two days, was that one patient contracted the disease and died within twelve hours after the contagion had been brought to the Island, while another died within twenty-four hours afterward. The mortality was not so great among patients treated in pavilions as among those treated in the hospital proper. In two cases of pregnancy the child died, in one Caesarean section having been performed. It was also remarked that the excretions of one of the pregnant women who had the cholera were cold.

Dr. JANEWAY said, in closing the discussion, that the only explanation which suggested itself to him of the uniform presence of bile in the gall-bladder in the cases examined by Dr. Dwyer was that possibly the bile was left dry by the excessive discharge of fluid during the course of the disease.

Typhoid Fever.—Dr. JANEWAY then presented parts of the intestine from two patients who had had typhoid fever, in the one case the lesions being very trifling indeed (only three patches of ulceration), and in the other very extensive. In the former case the patient died in a convulsion due to Bright's disease. In the latter case the temperature at first was low, and did not present the so-called characteristic temperature of typhoid fever; but it afterward rose to 103° or 104° F. Not infrequently typhoid fever was mistaken for malarial fever, and it was often difficult to make a positive diagnosis. Cases of typhoid fever during the present year might be said to be characterized by the absence of diarrhoea, and the small number of ulcers which formed in the intestines might often explain this clinical fact. But it was common to give patients suffering from typhoid fever a milk diet, and that in itself would tend to prevent diarrhoea.

Dr. S. T. HUBBARD inquired whether Dr. Janeway would expect to find extensive lesions in the intestine in cases of typhoid fever with a high temperature.

Dr. JANEWAY replied, Not necessarily.

NEW YORK PATHOLOGICAL SOCIETY.

Meeting of November 12, 1884.

The Vice-President, Dr. VAN GIESON, in the chair.

Carcinoma of the Breast.—Dr. WILCOX presented a scirrhous tumor of the breast.

Dr. GARRISH inquired whether any of the members had known a patient to live ten years after removal of a cancerous breast. The late Dr. Valentine Mott, he said, had never known a patient to live longer than six years.

Dr. WYETH had operated seven years before, and the patient was still living.

Dr. CARPENTER had assisted at an operation eight years before, and there had been no return.

Pachymeningitis Hæmorrhagica, with Cerebral Hæmorrhage.—Dr. DIXON presented a specimen, and related the history of a case, that of a man thirty-three years of age, who entered Charity Hospital October 27, 1884. He had been a hard drinker for some years. About six months before, while at

Madagascar, he had what he termed chills and fever, with headache and some epigastric pain. The headache was of a burning character. He had had some venereal disease. When Dr. Dixon saw him, November 3d, he was easily aroused, but was drowsy; the pupils were a little enlarged, but equally. September 27th he had fallen down stairs, striking the left side of the head, but there was no sign of fracture. The grasp of the right hand was weaker than that of the left; the patellar reflex on the right side was exaggerated. The diagnosis lay between four conditions: meningeal hæmorrhage, cerebral hæmorrhage, pachymeningitis interna hæmorrhagica, and syphilitic tumor. At the autopsy the upper surface of the left hemisphere was found to be covered by a false membrane, the result, apparently, of old pachymeningitis hæmorrhagica, and in the parietal region a fresh hæmorrhage had taken place. The condition was probably due to military aneurysms, although the examination which had been made had not revealed their presence. The kidneys and heart were normal.

Dr. SEGIN thought the case interesting because of the slight symptoms which had been present, and in that respect it resembled two cases which he had seen, in which the patients complained of severe headache. The first patient became comatose, but not paralytic. The autopsy revealed hæmorrhagic clots over both hemispheres. In the second case there were clonic spasms, but there was no paresis, and the patient finally died comatose. In this case the large quantity of blood in the cranial cavity had depressed the cerebral convolutions, making them appear concave instead of convex. Military aneurysms could usually be discovered by sacrificing the specimen, allowing it to decompose in water.

Dr. PEARODY said the case was further interesting from the comparative youth of the patient. Last spring he made an autopsy on a boy nineteen years of age, and found cerebral hæmorrhage, but in that case the aorta was abnormally small, and there were military aneurysms at the site of the hæmorrhage. Pachymeningitis hæmorrhagica might not give rise to symptoms until a large hæmorrhage took place.

Dr. VAN SANTVOORD thought sufficient stress had not been laid upon the fall which the patient had sustained in Dr. Dixon's case. When an *interne* in Bellevue Hospital he used to see patients with symptoms like those described by Dr. Dixon, but also giving a history of alcoholism as well as of a fall, and their condition might have been regarded as due to alcoholism, but that the autopsy showed fracture at the base of the skull (which, however, seemed not to have given rise to the symptoms) and hæmorrhage on the convexity.

Goitre.—Dr. WYETH presented a goitre attached to the trachea which had been partially removed by operation. The patient was thirty-six years of age, a native of Germany, and had carried the goitre since she was ten years of age, but had suffered no inconvenience from it until three years ago, when it began to develop rapidly and pressed upon the larynx, interfering with respiration, and giving rise to cough, with pain and headache. The tumor was found to be very vascular, and, after about three hours' steady work, the patient being all the while under the influence of ether, the operation for its removal was discontinued. A large number of ligatures had been applied. The patient lived two hours.

Removal of the Kidney for Pyelo-nephrosis.—Dr. H. C. COZ presented some specimens from a patient at the Woman's Hospital, who had a movable abdominal tumor which disappeared at times after the discharge of a large quantity of urine. An exploratory incision was made, and a kidney, the seat of hydro-nephrosis, was removed. Peritonitis developed, and the patient died eight days after the operation. Very little urine was secreted toward the close of life, and it contained traces of

albumin and casts. The autopsy showed that the ureter had slipped from the ligature, and some of the veins had also retracted, giving rise to slight hæmorrhage underneath the peritoneum. The only apparent cause for the collection of the fluid in the renal cyst was a valve-like fold of the mucous membrane at the entrance of the ureter into the pelvis of the kidney. An interesting fact in the case was that it showed the condition of the pelvic organs during menstruation. They were all highly congested. The uterine sinuses were gorged with blood, and resembled a sponge. The lining membrane was covered by a film, composed of epithelium and blood corpuscles, which could be lifted with the forceps.

Dr. PEABODY said, with reference to a question raised regarding uræmia, that he thought too much stress had been laid upon the presence of urea as a cause. The condition known as uræmia he thought had been proved to be independent of the retention of urea in the economy. It had been shown that more urea could be injected into the veins of a dog at a single sitting than a human being could retain through any diseased process of the kidneys, without producing uræmic symptoms.

Dr. SEGUN had been of the same opinion, but recently it would seem to have been shown that uræmia could be produced by the hypodermic injection of urea.

Dr. WENDT thought urea could not be said to have no connection with the production of uræmia. Even its hypodermic injection in dogs did give rise to symptoms, although they were not exactly like those of uræmia in the human subject.

Dr. PEABODY said that one fact which favored his opinion was that in the fowl urea was excreted by the intestine after occlusion of the ureter, and he doubted not the same was true in man.

Anæsthesia of the Trigemini, Occipitalis Major, and Cervical Plexus, with so-called Trophic Ulcer of the External Ear.—Dr. SEGUN, by the courtesy of Dr. Pomeroy, presented a young man suffering from a perforating ulcer of the ear which had developed after the existence of anæsthesia in the region of distribution of the trigemini, occipitalis major, and a branch of the cervical plexus. Dr. Segun referred to the old theory which assigned ulceration in anæsthetic regions to a trophic or nervous origin, and cited the experiments which went to prove that anæsthesia simply favored ulceration or the development of sores after traumatism.

Congenital Inguinal Kidney.—Dr. WENDT presented an inguinal kidney which he had removed from the body of a woman who died of senile changes at St. Francis's Hospital, in her eighty-seventh year. She denied having ever been sick, but had worn a truss for a supposed hernia. There was no visible pelvis of the kidney; the ureter was greatly shortened; there was no supra-renal capsule in connection with it; the renal artery did not spring from the abdominal aorta. The other kidney was in its normal position.

Endarteritis Obliterans.—Dr. PEABODY presented a part of the circle of Willis and some other small arteries at the base of the brain, from the body of a man, thirty-eight years of age, who was brought to the New York Hospital the 1st of November, unable to speak. He was intelligent, and there was no paralysis of motion or of sensation. There was exaggerated patellar reflex on the right side. The aphasia was distinctly ataxic. The following morning there was complete right hemiplegia. After two days there was a rise of temperature in the evening, which disappeared in the morning. The fourth day attacks of pulmonary œdema developed, in one of which the patient died. Just before death the temperature rose to 108° F. The urine was normal. At the autopsy the lumen of the basilar artery was found greatly obstructed by endarteritis obliterans. There was a small spot of softening in the left corpus striatum

and internal capsule. The blood-vessels in this region, on both sides, were distinctly calcareous. The left Sylvian artery was normal.

Aneurysm of the Arch of the Aorta; Pneumonia.—Dr. ROBINSON presented a specimen and related the history of a case of aneurysm of the arch of the aorta, pneumonia developing afterward which resulted in death. He directed special attention to the difficulty of recognizing the pneumonic condition in such cases, and said that it was liable, as in the present instance, to go unrecognized until revealed by the autopsy.

Tubercular Meningitis; Latent Catarrhal Phthisis.—Dr. VAN GIESON presented specimens which, he said, illustrated in a remarkable degree the conservative and curative processes of nature unaided by the physician's skill or art, and also illustrated the aphorism of Niemeyer, that the greatest danger to a phthisical subject was the development of tubercles. The patient was a laborer whom he first saw November 5th, when he was in active delirium. There was no special elevation of the temperature; there was very marked condensation at the right apex. The man became violent, and was sent to St. Catherine's Hospital, where he remained in a state of partial coma, varied by active delirium. He complained of severe pain in the head. The autopsy showed the appearances usually seen in tubercular meningitis. The upper portion of the right lung and the lower portion of the left were almost completely filled with calcified material, the result of an old catarrhal phthisis, from which the man had perfectly recovered. He had been well during the last thirteen years until his last illness.

Meeting of November 26, 1884.

The President, Dr. GEORGE F. SHRADY, in the chair.

A Coccyx removed by Operation.—Dr. WYETH presented a coccyx which he had removed from a man thirty-six years of age, who, four years ago, sustained an injury by falling backward on the ice. No symptoms were noticed at the time of the fall, but a few months later the patient was seized with spasms of the sphincter-ani muscle, which condition grew worse, and led to two operations for fissure of the anus, the first operation being by the knife, and the second by stretching of the sphincter. Dr. Wyeth recognized displacement of the coccyx by the fact that the stools were flattened and grooved, evidently on account of some obstruction. He afterward operated upon the same patient for inguinal hernia by Heaton's method. The patient was still a monomaniac on the subject of his rectal trouble, but Dr. Wyeth thought that there would finally be entire cessation of the symptoms.

A Modification of Otis's Urethrotome.—Dr. WYETH also presented Otis's urethrotome, which he had so modified by means of a ratchet that, when cutting through even the densest tissue, the extent of the incision could be restricted within absolute limits.

Dr. PEABODY had, during the past summer, removed the coccyx in a case of coccygodynia without giving relief from the symptoms; but the woman was afterward cured by measures directed against neuralgia.

Dr. GARRISH had cured the symptoms in several cases of injury to the coccyx by dividing the nerves subcutaneously close to the bone.

Dr. CARPENTER said that Dr. Goodell, of Philadelphia, after operating both in cases due to injury and in those due to neuralgia, had reached the conclusion that in cases of coccygodynia the operation which promised the best results was removal of the bone, whereas in essentially neuralgic cases anti-neuralgic measures should be resorted to.

Pulmonary Gangrene in Pneumonia.—Dr. HOLT presented the lungs of a boy, three years of age, who died, after two weeks'

illness, with pneumonic symptoms. The child had always been very healthy, and had never had any sickness except a bronchitis in its first year. At the autopsy a sacculated pleurisy, with turbid serous effusion, was found over the middle of the right lung behind; both lungs were firmly adherent to the chest walls, the right one especially. There was extensive formation of new membrane over the entire surface of the right lung. The upper lobe showed only congestion and œdema. The upper portion of the lower lobe presented the usual gross appearances of broncho-pneumonia. At the base were two large, irregular areas, dark in color, grayish at the borders, which, when cut into, were found to contain gangrenous spots, varying in size from that of a walnut to that of a pea. The contents could be washed away with a moderate stream of water. There was no marked separation between the necrotic and the living tissue. The areas of gangrene did not correspond to the distribution of the pulmonary artery, but to that of the bronchi. The bronchi were much inflamed. The heart was normal. The kidneys were enlarged, light in color, and soft, and the markings were quite indistinct. There was nothing to attract attention to the urine during life, but that remaining in the bladder after death was found to contain albumin and casts. Dr. Holt was not inclined to think there was any connection between the occurrence of gangrene in the lung and the disease of the kidneys. He quoted the literature of gangrene of the lung occurring during the course of pneumonia, and said that such cases were very rare indeed, and were found less frequently in children than in persons more advanced in years.

Urea not a Cause of Uræmia.—Dr. PEABODY said that at the last meeting of the society he had expressed the opinion that too much stress had been laid upon urea as a cause of uræmia, his opinion being based more or less upon observations in the lower animals. Dr. Seguin had been of a similar belief, but spoke of experiments recently made, from which it would seem that uræmic symptoms might be produced in the lower animals by the injection of urea into the blood. Dr. Seguin had since informed Dr. Peabody where he could gain access to the records of the experiments to which he had referred, and Dr. Peabody took occasion to show to the society that it would require, according to the amount of urea necessary in these experiments to produce death by injection into the circulation of the dog, one pound and a half of urea to produce a fatal result in man. But it had been shown that in a man of one hundred and fifty pounds weight, dying of uræmia occurring in the course of kidney disease, the blood contained only nine one-thousandths of a pound of urea. There might be apparent fallacies in this manner of drawing conclusions, but he thought it showed very conclusively that such experiments upon animals could give us little useful information as to the cause of uræmia in man. The injection into the blood of benzoate of sodium or of sulphate of sodium, agents which were not in themselves poisonous, would likewise produce uræmic symptoms. The experiments cited went no further than to show that the injection of a certain amount of any foreign substance into the circulation would produce death; they did not show that uræmia was due to the presence of urea in the circulation. He had seen several fatal cases in which there had been entire suppression of the urine, but none of the so-called uræmic symptoms.

Abscess of the Liver with Obscure Symptoms.—Dr. PEABODY also related the history of a case, and presented specimens, there being certain indefinite symptoms leading him to suppose that the man had once had typhoid fever, and that his last illness was due to a relapse of that disease, but the autopsy showed two abscesses of the liver, the larger containing half a pint of pus; there were also ulcers of the large intestine. The stools during life had presented the ordinary appearance of stools after

the taking of compound cathartic pills, which the patient had received for constipation.

When asked as to the cause of the abscesses, Dr. Peabody replied that they were undoubtedly due to the absorption of septic matter from the intestinal lesions.

Sarcoma of the Kidney.—Dr. FERGUSON presented a kidney, the seat of sarcoma, supposed to be congenital, removed by operation from a child four years of age. The history of the case had already been put on record by Dr. Little.

Dr. FERGUSON also presented a sarcoma of the first phalanx of the right ring-finger, following an injury, which contained a large number of so-called giant cells.

In reply to a question by Dr. Wyeth, Dr. PEABODY and Dr. NORTHCOTE said that it was very seldom that a case of congenital sarcoma came under observation.

Secondary Aneurysm of the Abdominal Aorta.—Dr. DIXON presented an aneurysm of the abdominal aorta, removed from the body of a woman twenty-six years of age, who was admitted to the hospital November 18th, and died on the 21st. Her father died of phthisis, and her brothers and sisters died young. There was no history of syphilis. Since last spring she had been treated in St. Luke's Hospital for femoral aneurysm, which was reduced by pressure and she was discharged cured. Three months ago her courses ceased, the appetite failed, and there was nausea, with some vomiting. A month ago the patient noticed a lump in the abdomen, which pulsated. She was weak, anæmic, and constipated, vomited a great deal, and could not sleep, because of pain. Physical examination revealed a systolic heart murmur, and a pulsating tumor in the epigastric region, which was the seat of a distinct impulse synchronous with the second sound of the heart. The tumor had a marked thrill, with a double *bruit*. The patient died in collapse. At the autopsy there was found an aneurysm of the abdominal aorta, near the celiac axis. Nearly the entire wall of the aorta was involved in the sac, and anteriorly there was a rupture about half an inch in circumference. Above the aneurysm was an atheroma, and below a constriction of the vessel scarcely admitting the little finger.

Fibroid Tumors of the Uterus.—Dr. COE presented two uteri with fibroids, one of which had been removed by abdominal section, the other at an autopsy. In the latter case Hegar's operation had been performed. One of the tumors presented a large cicatrix upon its anterior surface, leading to the inference that it had sustained some previous injury. No history of such injury had been obtained. Dr. Coe remarked that in the case of hysterectomy the pedicle had been treated by the intraperitoneal method, which he regarded as inferior to the extraperitoneal, judging by the favorable results which he had observed in German clinics, where the latter procedure was generally adopted. There was always great danger of septicæmia when such a large stump was returned to the abdominal cavity.

Miscellany.

THERAPEUTICAL NOTES.

Experiments on the Antiseptic Action of the Salts of Copper.—M. Bochefontaine ("Gaz. hebdomadaire de médecine et de chirurgie") publishes the results of a series of experiments undertaken principally with the idea of testing the alleged value of copper as a prophylactic of cholera. He concludes that, although a solution of sulphate of copper of a strength of one to one hundred may not prevent the development of certain vegetable spores, it will arrest the growth of the vibrios. A solution of one to one thousand, however, does not check the development of the latter.

Hypodermic injections of the salt do not arrest the course of parasitic diseases induced artificially in animals. The practical deduction is that, even if sulphate of copper does act upon the contagious element of cholera, it has no influence upon the vibrios or microbic germs.

Kairine in the Treatment of Yellow Fever.—Dr. Naegeli, of Rio de Janeiro ("Berlin. klin. Woch."), states that, in seven severe cases of yellow fever treated with this drug, five patients recovered. He gave fifteen grains hourly so long as the temperature remained high. Even black vomit does not contra-indicate the use of kairine. He states that the delirium disappeared, the patients enjoyed a refreshing sleep, and convalescence was uninterrupted and rapid. Besides kairine, the patients received nothing but iced drinks.

The Purity of Iodoform.—The "Gazzetta degli Ospitali" contains an article on this subject in which the following test is mentioned: Stir up the iodoform in a quantity of distilled water, and add to the filtrate an alcoholic solution of nitrate of silver. If a precipitate of reduced silver is deposited within twenty-four hours, it proves that some foreign substance is present. Pure iodoform, the writer states, if kept for some time exposed to air and light, acquires toxic properties.

Rosinol.—Gautrelet ("Gaz. hebdomadaire de médecine et de chirurgie.") describes this substance as a yellowish, oily fluid, of a peculiar odor, having the composition $H_{12}O_{23}$. It contains a number of bodies, such as terebene, colophene, cresylic and phenic acids, and creasote; hence its combined tonic, antiseptic, and astringent powers. The writer recommends rosinol as an external application, especially in surgical dressings. He says that it has a specific action in elytritis and endometritis, and remarks that it is very useful in obstetrics. Internally, it is a valuable agent in the treatment of typhoid fever, cancer and ulcer of the stomach, and, in fact, in all lesions of the gastro-intestinal mucous membrane. By reason of its marked astringent action it is particularly indicated in catarrhal affections of the respiratory tract.

Beech-Creasote in Pulmonary Affections.—In the same journal Dr. Lasné recommends a combination of creasote, balsam of tolu, and Norway tar in the treatment of pulmonary affections. He gives the following formula:

Pure beech-creasote.....	1 minim;
Purified Norway tar,	
Balsam of tolu, each.....	1-5 minim.

Inclose in a capsule. In incipient phthisis, two such capsules should be given morning and evening. In advanced cases the number of capsules may be increased to twelve daily.]

Lactate of Iron.—The "Union médicale" publishes the report of a commission appointed by the *Académie de médecine* to examine into the therapeutic value of this preparation. The report speaks in the highest terms of the lactate, as being one of the most useful of the preparations of iron. The dose recommended is from six to twelve grains daily.

Arsenic in Pulmonary Tuberculosis.—Leyden ("Gaz. hebdomadaire de médecine et de chirurgie.") has employed this remedy in twenty cases without results. He states that he was unable to perceive the slightest influence upon either the general or the local condition of the patients.

Hippurate of Lithium.—In the same journal Poulet continues his article on the hippurates, to which we lately called attention. He recommends the following preparation in the treatment of gravel:

Carbonate of lithium.....	40 grains;
Hippuric acid.....	9 drachms;
Warm water.....	30 ounces;
Sugar.....	40 "

By the resulting reaction hippurate of lithium is formed, and each teaspoonful of the mixture will contain four grains of that salt. M. Poulet states that hippurate of lime is the best antidote in carboic-acid poisoning that we possess, being far superior to the saccharate.

Apomorphine in Nervous Affections.—Dr. Weill ("Lyon médical") has used this drug in several cases, and summarizes his results as follows: 1. The hydrochlorate, given hypodermically, in doses of from one thirtieth to one tenth of a grain, has a favorable action in various spasmodic affections, such as obstinate hiccough. 2. It also acts well in cases of a convulsive character, such as epilepsy and chorea. 3. By using the drug carefully, the sedative effects may be produced without the nauseating action.

Submucous Injections of Chloroform.—M. Gaspard Guillot contributes his personal observations on this subject in a letter to the "Progrès médical." He recommends the treatment in cases of obstinate dental neuralgia and alveolar abscess. Two or three drops should usually be injected at a time. The writer refers to the extensive experience of Dr. Doss, who has given a large number of the injections, with perfect success. The pain was quickly subdued, and no bad results followed.

Hamamelis.—Dujardin-Beaumetz ("Bull. gén. de thérap.") suggests the following as a convenient formula for the administration of this drug as a remedy for hemorrhoids:

Fluid extract of hamamelis,	
Syrup of bitter orange-peel, each.....	3 ss;
Tincture of vanilla.....	gtt. xx.

Dose, a teaspoonful.

A Suppository for Anal Fissure.—M. J. Simon ("Union médicale") gives this formula:

Extract of belladonna.....	1 drachm;
Poplar ointment *.....	2 drachms;
Cocoa butter.....	q. s.

Divide into fifteen suppositories. One to be used every night.

Nothnagel on the Treatment of Fever.—The "Deutsche Medizinische Zeitung" publishes an address delivered by Professor Nothnagel before the Society of Physicians of Vienna, the subject of which is so important that we transcribe a few of the sentences. Speaking of the needless alarm felt by physicians at the presence of a moderately high temperature, Nothnagel says: "I would not neglect this opportunity of lifting up my voice in this place against the (I can give it no other name) *abuse*, which has prevailed almost universally in practice, of wishing to treat fever *à tout prix*. If the physician is called to a patient who fell ill yesterday, and to-day has a temperature of 38-5° C. [101° F.] or 38-7° [101-6°]—a positive diagnosis can not be made, since no certain local affection is yet to be discovered—his treatment consists in ordering quinine or some other antipyretic. In order not to do any harm, a small dose is prescribed, but, at any rate, quinine is given, with the idea that the fever must be opposed. . . . I am firmly convinced, and hope, that this false and erroneous use of quinine which is at present the fashion will after a time again disappear. I need not remark that, as quinine is administered in the majority of cases, it is perfectly useless for the lowering of the temperature. One, two, three, five decigrammes—even a gramme, when distributed over the twenty-four hours—have no effect; on the contrary, actual harm is done. . . . According to my conviction, with which many other investigators agree, fever, in a very large number of cases, belongs to the most beneficial influences, to those phenomena and processes of reaction which we may regard as compensatory. What rôle these compensatory processes play we know not. . . . Temperatures which exceed 40° C. [104° F.] must however, be energetically controlled, but temperatures of 39° [102-2° F.] do not require such vigorous treatment, especially in diseases which run a brief course. In short, it may be said that a temperature which does not exceed 40° C. [104° F.] does not injure the patient."

Albuminuria as Contra-indicating Ovariectomy.—Dr. R. W. Wilcox, of New York ("St. Louis Med. and Surg. Jour."), in an interesting article on this subject, compares the results of his own clinical observations with those of a large number of prominent authorities. He distinguishes between albuminuria due to chronic Bright's disease and that form which is occasioned or aggravated by the mechanical pressure of the tumor. A simple albuminuria, he concludes, should certainly not be considered as a contra-indication, since it may be caused by the presence of the tumor. Given even a parenchymatous nephritis, this may be, and probably is, increased by the tumor, and the surgeon should not on this ground deny the patient her only chance for life. In the light of the few statistics which we have, and of the great number of cases—many of which must be complicated with renal disease—in which the operation is successfully undergone, we have no reason to regard albuminuria as a weighty contra-indication.

* An ointment made from fresh poplar-buds and the leaves of the poppy, belladonna, hyoscyamus, and *Solanum nigrum*.

INDEX TO VOLUME XL.

Abdomen, A Wound of the, involving the Umbilicus, followed by Hematoma.	301	Antisepsis, A Classification of.	168	ARMY, MEDICAL OFFICERS OF THE:	
Abdominal Section; its Value and Range of Application.	414	Antisepsis in Midwifery.	481, 498	Wolverton, W. D.	464
